THIRD EDITION

HANDBOOK OF  
PLANT AND  
CROP STRESS

## BOOKS IN SOILS, PLANTS, AND THE ENVIRONMENT

### Editorial Board

|                                    |                                                                                                                            |
|------------------------------------|----------------------------------------------------------------------------------------------------------------------------|
| <i>Agricultural Engineering</i>    | Robert M. Peart, University of Florida, Gainesville                                                                        |
| <i>Crops</i>                       | Mohammad Pessarakli, University of Arizona, Tucson                                                                         |
| <i>Environment</i>                 | Kenneth G. Cassman, University of Nebraska, Lincoln                                                                        |
| <i>Irrigation and Hydrology</i>    | Donald R. Nielsen, University of California, Davis                                                                         |
| <i>Microbiology</i><br>Wageningen, | Jan Dirk van Elsas, Research Institute for Plant Protection,<br>The Netherlands                                            |
| <i>Plants</i><br>Maryland          | L. David Kuykendall, U.S. Department of Agriculture, Beltsville,<br><br>Kenneth B. Marcum, Arizona State University, Tempe |
| <i>Soils</i>                       | Jean-Marc Bollag, Pennsylvania State University, University Park<br>Tsuyoshi Miyazaki, University of Tokyo, Japan          |

*Soil Biochemistry, Volume 1*, edited by A. D. McLaren and G. H. Peterson

*Soil Biochemistry, Volume 2*, edited by A. D. McLaren and J. Skujins

*Soil Biochemistry, Volume 3*, edited by E. A. Paul and A. D. McLaren

*Soil Biochemistry, Volume 4*, edited by E. A. Paul and A. D. McLaren

*Soil Biochemistry, Volume 5*, edited by E. A. Paul and J. N. Ladd

*Soil Biochemistry, Volume 6*, edited by Jean-Marc Bollag and G. Stotzky

*Soil Biochemistry, Volume 7*, edited by G. Stotzky and Jean-Marc Bollag

*Soil Biochemistry, Volume 8*, edited by Jean-Marc Bollag and G. Stotzky

*Soil Biochemistry, Volume 9*, edited by G. Stotzky and Jean-Marc Bollag

*Organic Chemicals in the Soil Environment, Volumes 1 and 2*, edited by C. A. I. Goring  
and J. W. Hamaker

*Humic Substances in the Environment*, M. Schnitzer and S. U. Khan

*Microbial Life in the Soil: An Introduction*, T. Hattori

*Principles of Soil Chemistry*, Kim H. Tan

*Soil Analysis: Instrumental Techniques and Related Procedures*, edited by  
Keith A. Smith

*Soil Reclamation Processes: Microbiological Analyses and Applications*, edited by  
Robert L. Tate III and Donald A. Klein

*Symbiotic Nitrogen Fixation Technology*, edited by Gerald H. Elkan

*Soil–Water Interactions: Mechanisms and Applications*, Shingo Iwata and Toshio Tabuchi with Benno P. Warkentin

*Soil Analysis: Modern Instrumental Techniques*, Second Edition, edited by Keith A. Smith

*Soil Analysis: Physical Methods*, edited by Keith A. Smith and Chris E. Mullins

*Growth and Mineral Nutrition of Field Crops*, N. K. Fageria, V. C. Baligar, and Charles Allan Jones

*Semiarid Lands and Deserts: Soil Resource and Reclamation*, edited by J. Skujins

*Plant Roots: The Hidden Half*, edited by Yoav Waisel, Amram Eshel, and Uzi Kafkafi

*Plant Biochemical Regulators*, edited by Harold W. Gausman

*Maximizing Crop Yields*, N. K. Fageria

*Transgenic Plants: Fundamentals and Applications*, edited by Andrew Hiatt

*Soil Microbial Ecology: Applications in Agricultural and Environmental Management*, edited by F. Blaine Metting, Jr.

*Principles of Soil Chemistry*, Second Edition, Kim H. Tan

*Water Flow in Soils*, edited by Tsuyoshi Miyazaki

*Handbook of Plant and Crop Stress*, edited by Mohammad Pessarakli

*Genetic Improvement of Field Crops*, edited by Gustavo A. Slafer

*Agricultural Field Experiments: Design and Analysis*, Roger G. Petersen

*Mechanisms of Plant Growth and Improved Productivity: Modern Approaches*, edited by Amarjit S. Basra

*Selenium in the Environment*, edited by W. T. Frankenberger, Jr. and Sally Benson

*Plant–Environment Interactions*, edited by Robert E. Wilkinson

*Handbook of Plant and Crop Physiology*, edited by Mohammad Pessarakli

*Handbook of Phytoalexin Metabolism and Action*, edited by M. Daniel and R. P. Purkayastha

*Soil–Water Interactions: Mechanisms and Applications*, Second Edition, Revised and Expanded, Shingo Iwata, Toshio Tabuchi, and Benno P. Warkentin

*Stored-Grain Ecosystems*, edited by Digvir S. Jayas, Noel D. G. White, and William E. Muir

*Agrochemicals from Natural Products*, edited by C. R. A. Godfrey

*Seed Development and Germination*, edited by Jaime Kigel and Gad Galili

*Nitrogen Fertilization in the Environment*, edited by Peter Edward Bacon

*Phytohormones in Soils: Microbial Production and Function*, William T. Frankenberger, Jr. and Muhammad Arshad

*Handbook of Weed Management Systems*, edited by Albert E. Smith

*Soil Sampling, Preparation, and Analysis*, Kim H. Tan

*Soil Erosion, Conservation, and Rehabilitation*, edited by Menachem Agassi

*Plant Roots: The Hidden Half*, Second Edition, Revised and Expanded, edited by Yoav Waisel, Amram Eshel, and Uzi Kafkafi

*Photoassimilate Distribution in Plants and Crops: Source–Sink Relationships*, edited by Eli Zamski and Arthur A. Schaffer

*Mass Spectrometry of Soils*, edited by Thomas W. Boutton and Shinichi Yamasaki

*Handbook of Photosynthesis*, edited by Mohammad Pessarakli

*Chemical and Isotopic Groundwater Hydrology: The Applied Approach*, Second Edition, Revised and Expanded, Emanuel Mazor

*Fauna in Soil Ecosystems: Recycling Processes, Nutrient Fluxes, and Agricultural Production*, edited by Gero Benckiser

*Soil and Plant Analysis in Sustainable Agriculture and Environment*, edited by Teresa Hood and J. Benton Jones, Jr.

*Seeds Handbook: Biology, Production, Processing, and Storage*, B. B. Desai, P. M. Kotecha, and D. K. Salunkhe

*Modern Soil Microbiology*, edited by J. D. van Elsas, J. T. Trevors, and E. M. H. Wellington

*Growth and Mineral Nutrition of Field Crops*, Second Edition, N. K. Fageria, V. C. Baligar, and Charles Allan Jones

*Fungal Pathogenesis in Plants and Crops: Molecular Biology and Host Defense Mechanisms*, P. Vidhyasekaran

*Plant Pathogen Detection and Disease Diagnosis*, P. Narayanasamy

*Agricultural Systems Modeling and Simulation*, edited by Robert M. Peart and R. Bruce Curry

*Agricultural Biotechnology*, edited by Arie Altman

*Plant–Microbe Interactions and Biological Control*, edited by Greg J. Boland and L. David Kuykendall

*Handbook of Soil Conditioners: Substances That Enhance the Physical Properties of Soil*, edited by Arthur Wallace and Richard E. Terry

*Environmental Chemistry of Selenium*, edited by William T. Frankenberger, Jr., and Richard A. Engberg

*Principles of Soil Chemistry*, Third Edition, Revised and Expanded, Kim H. Tan

*Sulfur in the Environment*, edited by Douglas G. Maynard

*Soil–Machine Interactions: A Finite Element Perspective*, edited by Jie Shen and Radhey Lal Kushwaha

*Mycotoxins in Agriculture and Food Safety*, edited by Kaushal K. Sinha and Deepak Bhatnagar

*Plant Amino Acids: Biochemistry and Biotechnology*, edited by Bijay K. Singh

*Handbook of Functional Plant Ecology*, edited by Francisco I. Pugnaire and Fernando Valladares

*Handbook of Plant and Crop Stress*, Second Edition, Revised and Expanded, edited by Mohammad Pessarakli

*Plant Responses to Environmental Stresses: From Phytohormones to Genome Reorganization*, edited by H. R. Lerner

*Handbook of Pest Management*, edited by John R. Ruberson

*Microbial Endophytes*, edited by Charles W. Bacon and James F. White, Jr.

*Plant–Environment Interactions*, Second Edition, edited by Robert E. Wilkinson

*Microbial Pest Control*, Sushil K. Khetan

*Soil and Environmental Analysis: Physical Methods*, Second Edition, Revised and Expanded, edited by Keith A. Smith and Chris E. Mullins

*The Rhizosphere: Biochemistry and Organic Substances at the Soil–Plant Interface*, Roberto Pinton, Zeno Varanini, and Paolo Nannipieri

*Woody Plants and Woody Plant Management: Ecology, Safety, and Environmental Impact*, Rodney W. Bovey

*Metals in the Environment*, M. N. V. Prasad

*Plant Pathogen Detection and Disease Diagnosis*, Second Edition, Revised and Expanded, P. Narayanasamy

*Handbook of Plant and Crop Physiology*, Second Edition, Revised and Expanded, edited by Mohammad Pessarakli

*Environmental Chemistry of Arsenic*, edited by William T. Frankenberger, Jr.

*Enzymes in the Environment: Activity, Ecology, and Applications*, edited by Richard G. Burns and Richard P. Dick

*Plant Roots: The Hidden Half*, Third Edition, Revised and Expanded, edited by Yoav Waisel, Amram Eshel, and Uzi Kafafi

*Handbook of Plant Growth: pH as the Master Variable*, edited by Zdenko Rengel

*Biological Control of Major Crop Plant Diseases* edited by Samuel S. Gnanamanickam

*Pesticides in Agriculture and the Environment*, edited by Willis B. Wheeler

*Mathematical Models of Crop Growth and Yield*, Allen R. Overman and Richard Scholtz

*Plant Biotechnology and Transgenic Plants*, edited by Kirsi-Marja Oksman Caldentey and Wolfgang Barz

*Handbook of Postharvest Technology: Cereals, Fruits, Vegetables, Tea, and Spices*, edited by Amalendu Chakraverty, Arun S. Mujumdar, G. S. Vijaya Raghavan, and Hosahalli S. Ramaswamy

*Handbook of Soil Acidity*, edited by Zdenko Rengel

*Humic Matter in Soil and the Environment: Principles and Controversies*, edited by Kim H. Tan

*Molecular Host Plant Resistance to Pests*, edited by S. Sadasivam and B. Thayumanayan

*Soil and Environmental Analysis: Modern Instrumental Techniques*, Third Edition, edited by Keith A. Smith and Malcolm S. Cresser

*Chemical and Isotopic Groundwater Hydrology*, Third Edition, edited by Emanuel Mazor

*Agricultural Systems Management: Optimizing Efficiency and Performance*, edited by Robert M. Peart and W. David Shoup

*Physiology and Biotechnology Integration for Plant Breeding*, edited by Henry T. Nguyen and Abraham Blum

*Global Water Dynamics: Shallow and Deep Groundwater, Petroleum Hydrology, Hydrothermal Fluids, and Landscaping*, , edited by Emanuel Mazor

*Principles of Soil Physics*, edited by Rattan Lal

*Seeds Handbook: Biology, Production, Processing, and Storage*, Second Edition, Babasaheb B. Desai

*Field Sampling: Principles and Practices in Environmental Analysis*, edited by Alfred R. Conklin

*Sustainable Agriculture and the International Rice–Wheat System*, edited by Rattan Lal, Peter R. Hobbs, Norman Uphoff, and David O. Hansen

*Plant Toxicology*, Fourth Edition, edited by Bertold Hock and Erich F. Elstner

*Drought and Water Crises: Science, Technology, and Management Issues*, edited by Donald A. Wilhite

*Soil Sampling, Preparation, and Analysis*, Second Edition, Kim H. Tan

*Climate Change and Global Food Security*, edited by Rattan Lal, Norman Uphoff, B. A. Stewart, and David O. Hansen

*Handbook of Photosynthesis*, Second Edition, edited by Mohammad Pessarakli

*Environmental Soil-Landscape Modeling: Geographic Information Technologies and Pedometrics*, edited by Sabine Grunwald

*Water Flow in Soils*, Second Edition, Tsuyoshi Miyazaki

*Biological Approaches to Sustainable Soil Systems*, edited by Norman Uphoff, Andrew S. Ball, Erick Fernandes, Hans Herren, Olivier Husson, Mark Laing, Cheryl Palm, Jules Pretty, Pedro Sanchez, Nteranya Sanginga, and Janice Thies

*Plant–Environment Interactions*, Third Edition, edited by Bingru Huang  
*Biodiversity in Agricultural Production Systems*, edited by Gero Benckiser  
and Sylvia Schnell  
*Organic Production and Use of Alternative Crops*, Franc Bavec and Martina Bavec  
*Handbook of Plant Nutrition*, edited by Allen V. Barker and David J. Pilbeam  
*Modern Soil Microbiology*, Second Edition, edited by Jan Dirk van Elsas,  
Janet K. Jansson, and Jack T. Trevors  
*Functional Plant Ecology*, Second Edition, edited by Francisco I. Pugnaire  
and Fernando Valladares  
*Fungal Pathogenesis in Plants and Crops: Molecular Biology and Host Defense  
Mechanisms*, Second Edition, P. Vidhyasekaran  
*Handbook of Turfgrass Management and Physiology*, edited by Mohammad Pessarakli  
*Soils in the Humid Tropics and Monsoon Region of Indonesia*, Kim H. Tan  
*Handbook of Agricultural Geophysics*, edited by Barry J. Allred, Jeffrey J. Daniels,  
and M. Reza Ehsani  
*Environmental Soil Science*, Third Edition, Kim H. Tan  
*Principles of Soil Chemistry*, Fourth Edition, Kim H. Tan  
*Handbook of Plant and Crop Stress*, Second Edition, edited by Mohammad Pessarakli

THIRD EDITION

# HANDBOOK OF PLANT AND CROP STRESS

Edited by  
Mohammad Pessarakli

# Contents

|                      |       |
|----------------------|-------|
| Preface.....         | xvii  |
| Acknowledgments..... | xxi   |
| Editor .....         | xxiii |
| Contributors .....   | xxv   |

## ***PART I Soil Salinity and Sodicity Problems***

|                  |                                                                                                         |    |
|------------------|---------------------------------------------------------------------------------------------------------|----|
| <b>Chapter 1</b> | Soil Salinity and Sodicity as Particular Plant/Crop Stress Factors.....                                 | 3  |
|                  | <i>Mohammad Pessarakli and I. Szabolcs</i>                                                              |    |
| <b>Chapter 2</b> | Soil Salinity Development, Classification, Assessment, and Management<br>in Irrigated Agriculture ..... | 23 |
|                  | <i>Shabbir A. Shahid and Khalil ur Rahman</i>                                                           |    |
| <b>Chapter 3</b> | Soil Salinization and Management Options for Sustainable Crop Production .....                          | 41 |
|                  | <i>Donald L. Suarez</i>                                                                                 |    |
| <b>Chapter 4</b> | Influence of Sodium on Soils in Humid Regions.....                                                      | 55 |
|                  | <i>Rafif K. Srour, Louis M. McDonald, V.P. (Bill) Evangelou</i>                                         |    |

## ***PART II Plant/Crop Tolerance and Stressful Conditions***

|                  |                                                                                                      |     |
|------------------|------------------------------------------------------------------------------------------------------|-----|
| <b>Chapter 5</b> | Oxidative Stress and Antioxidative Defense Systems in Plants Growing<br>under Abiotic Stresses ..... | 89  |
|                  | <i>Pallavi Sharma, Ambuj Bhushan Jha, and Rama Shanker Dubey</i>                                     |     |
| <b>Chapter 6</b> | Antioxidant Protection during Abiotic Stresses.....                                                  | 139 |
|                  | <i>Dagmar Procházková and Nad'a Wilhelmová</i>                                                       |     |
| <b>Chapter 7</b> | Biochemical Mechanisms for the Maintenance of Oxidative Stress<br>under Control in Plants.....       | 157 |
|                  | <i>Diego G. Arias, Claudia V. Piattoni, Sergio A. Guerrero, and Alberto A. Iglesias</i>              |     |

|                                                                                                                                                                                                           |                                                                                                                               |     |
|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------|-----|
| <b>Chapter 8</b>                                                                                                                                                                                          | Plant Hormone Functions in Abiotic and Biotic Stress Responses.....                                                           | 191 |
|                                                                                                                                                                                                           | <i>Radomíra Vanková</i>                                                                                                       |     |
| <b>Chapter 9</b>                                                                                                                                                                                          | Role of Proline in Plant Response to Drought and Salinity.....                                                                | 213 |
|                                                                                                                                                                                                           | <i>Bruria Heuer</i>                                                                                                           |     |
| <b>Chapter 10</b>                                                                                                                                                                                         | Role of Dehydrins in Plant Stress Response .....                                                                              | 239 |
|                                                                                                                                                                                                           | <i>Klára Kosová, Ilja Tom Prášil, and Pavel Vítámvás</i>                                                                      |     |

# Preface

The dynamic and ever-expanding knowledge of environmental stresses, and their effects on plants and crops, has resulted in the compilation of a large volume of information since the second edition of the *Handbook of Plant and Crop Stress* was presented to scientists and professionals. This fact necessitated that this unique, comprehensive source of information be revised and all the new findings in this field be included in this updated edition. Like the first and second editions, the new edition is a unique, comprehensive, and complete collection of the issues on stress imposed on plants/crops.

More than 80% of the materials in this edition are entirely new and have been included under new titles. The remaining 20% have been updated. Therefore, almost 90% of the materials are new, thus creating what could be considered a new version.

Out of the 47 chapters, only 11 have been taken from the second edition, but have been substantially revised and updated. The other 36 chapters are entirely new.

Since the early 1900s, soil/plant scientists have observed that plant growth and crop yields decreased under salinity, drought, and/or other environmental stress conditions. Reduction in plant growth was reported as a result of a modification in the physiological process and environmental conditions that control growth. Stresses imposed on plants due to pollution or applications of agrichemicals have recently attracted the attention of scientists, investigators, and environmentalists in agriculture and related areas. The mechanisms by which salinity, drought, high/low temperatures or heat, high/low pH, high/low light, nutrient deficiency, pollution, agrichemicals, climatic changes, or any other stresses affect plant metabolism, thereby reducing plant growth and development, are still not completely understood. Among plant physiological processes, the change in nutrient uptake and metabolism induced by salt, drought, and/or other stress factors is commonly accepted by scientists as one of the most important factors responsible for abnormal plant metabolism, reduced growth, and decreased crop yield. The need for minimizing the effects of salt, drought, extreme temperatures, extreme pH, extreme light, pollution, agrichemicals, climatic changes, or any other environmental stresses on plant growth and crop yield is vital. Thus, a greater awareness of these stress factors, and problems associated with them, is essential to scientists, producers, and all involved in the field of agriculture.

This handbook is a comprehensive, up-to-date reference book that addresses issues and concerns related to plant and crop stress effectively. While there are many reference books on soil salinity, sodicity, specific plant/crop salt and water stress, pollution, and other environmental stresses, all of these exist in relative isolation, covering only one specific topic.

To solve plant and crop stress problems efficiently and effectively requires the accountability and coordination of all the factors and their interrelationship with plant/crop stress. While several authors have competently covered the many areas separately, the areas are, nonetheless, interrelated and should be covered comprehensively in a single text. Thus, the purpose of this book is to fill this niche.

The new and updated third edition of the *Handbook of Plant and Crop Stress* has been written by more than 100 contributors from 27 countries, who are among the most competent and knowledgeable scientists, specialists, and researchers in the field of agriculture. It is intended to serve as a resource for preparing for lectures as well as for conducting research. Scientists, agricultural researchers, agricultural practitioners, and students will benefit from this unique comprehensive guide, which covers plant stress problems from the soil to the atmosphere.

As with other fields, accessibility of knowledge is among the most critical factors involved with crop stress problems. Without due consideration of all the elements contributing to a specific crop stress problem, it is unlikely that a permanent solution will be achieved. Therefore, this book covers as many of the factors as possible. To further facilitate the accessibility of the desired information

in the areas of stress covered in this collection, the book has been divided into 10 parts. These include Soil Salinity and Sodicity Problems; Plant/Crop Tolerance and Stressful Conditions; Plants and Crops Responses, Physiology, Cellular and Molecular Biology, and Microbiological Aspects under Salt, Drought, Heat, Cold, Light, and Other Stressful Conditions; Plant and Crop Responses to Pollution Stress; Plant and Crop Responses to Weeds, Pests, Pathogens, and Agrichemical Stress Conditions; Genetic Factors and Plant/Crop Genomics under Stress; Examples of Empirical Investigations of Specific Plants and Crops Grown in Salt, Drought, and Other Environmental Stress Conditions; Climatic Changes, Elevated Carbon Dioxide, and Plant/Crop Responses; Future Promises: Improving Plant and Crop Adaptation/Tolerance and Cultivation under Stressful Conditions; and Beneficial Aspects of Stress. Each of these parts consists of one or more chapters so as to discuss, independently, as many aspects of the stresses as possible.

Part I consists of four chapters, including “Soil Salinity and Sodicity as Particular Plant/Crop Stress Factors”; “Soil Salinity Development, Classification, Assessment, and Management in Irrigated Agriculture”; “Soil Salinization and Management Options for Sustainable Crop Production”; and “Influence of Sodium on Soils of Humid Regions”. These chapters explain soil as a medium of crop growth, soil salinity, and sodicity problems, as well as the effects of soil salinity and sodicity on plant/crop growth.

Part II consists of seven chapters as follows: “Oxidative Stress and Antioxidative Defense Systems in Plants Growing under Abiotic Stresses”; “Antioxidant Protection during Abiotic Stresses”; “Biochemical Mechanisms for the Maintenance of Oxidative Stress under Control in Plants”; “Plant Hormone Functions in Abiotic and Biotic Stress Responses”; “Role of Proline in Plant Response to Drought and Salinity”; “Role of Dehydrins in Plant Stress Response; and Behavior of Water in Plants at Low and Ultralow Temperatures”. These chapters address plants and crop mechanisms of stress tolerance.

Part III consists of the following 12 chapters: “Germination of Seeds and Propagules under Salt Stress”; “Response of Crop Plants to Nitrogen Stress: Opportunities to Increase Nitrogen Use Efficiency”; “Photosynthesis and Light Stress in a Model Plant: Role of Chloroplast Transporters”; “Photosynthetic Pigments Apparatus in the Northern Plants”; “Modifications of the Carotenoid Metabolisms in Plastids: A Response to Stress Conditions”; “Thermoluminescence Study of Photosystem II Activity in Resurrection Plant *Haberlea rhodopensis* during Desiccation”; “Carbon Metabolism and Plant Stress”; “Protein Synthesis by Plants under Stressful Conditions”; “Heat Shock Proteins and Acquisition of Thermotolerance in Plants”; “Effect of Low Temperatures on the Structure of Plant Cells: Structural, Biochemical, and Molecular Aspects”; “Effects of UV-B Radiation on Plants: Molecular Mechanisms Involved in UV-B Responses”; and “Effect of High Temperature and UV-A Radiation on Photosystem II”. Each of these chapters provides in-depth information on each of these topics.

Part IV consists of four chapters, including “Plant Responses to Toxic Metal Stress”; “Heavy Metal Pollution: Damage and Defense Strategies in Plants”; “Heavy Metals and Plastid Metabolism”; and “Plant Responses to Cadmium and Mercury Stress”. These chapters provide detailed information on plants/crops influenced by pollution generated from either the soil, water, or the atmosphere.

Part V also consists of four chapters as follows: “Stress in Plants and Crops Induced by Parasitic Weeds”; “Involvement of Insect Pests in Plant and Crop Stress”; “Stress in Plants and Crops Induced by Herbicide-Mediated Alteration in the Population and Activity of Root-Associated Microorganisms”; and “Stress in Plants and Crops Induced by Fungal Pathogens”. These chapters discuss the interactions between weeds, pests, pathogens, and agrichemicals, and plants/crops and the potential problems caused by the application of agrichemicals to plants/crops.

Part VI consists of three chapters, including “Genetic Factors Affecting Abiotic Stress Tolerance in Crops”; “Genetic Improvement of Cold Hardiness in Bermudagrass”; and “Candidate Gene Expression Involved in Plant Drought Resistance”. These chapters present detailed and comprehensive information of all available materials on these subjects.

Several examples of empirical investigations of specific plants and crops grown under salt, drought, and/or other stress conditions are covered in Part VII, which consists of five chapters, presenting various plants and crops with different degrees of tolerance. These chapters include “Responses of Green Beans (*Phaseolus vulgaris* L.) in Terms of Dry Matter Production, Nitrogen Uptake, and Water Absorption under Salt Stress Conditions”; “Physiology and Molecular Biology of the Effects of Salinity on Rice”; “Landscaping under Water Stress Conditions”; “Turfgrass Nutrient Management under Stresses: A Part of Integrated Stress Management”; and “Nutrient Management of Golf Course Putting Greens under Stresses”.

Due to recent climatic changes and increase in CO<sub>2</sub> levels, plant resistance to these changes must be considered for cultivation under these conditions. Therefore, Part VIII, which consists of a single chapter entitled “Plant Biomass and Stem Juice of the C<sub>4</sub> Sugarcane at Elevated Growth CO<sub>2</sub> and Temperature” presents the latest information on this subject.

Part IX provides evidence and guidance on plants and crops that can be used under stressful conditions. This part consists of the following six chapters: “Improving Crop Resistance to Abiotic Stresses through Seed Invigoration”; “Physiological and Biochemical Strategies Allowing Plants/Crops to Thrive under Ionic Stress”; “Role of *Acacia ampliceps* in Managing Salt-Affected Lands”; “Adaptive Strategies of Tropical Forage Grasses to Low Phosphorus Stress: The Case of Brachiariagrasses”; “Forgotten Link in Improving Crop Salt Tolerance Research under Brackish Irrigation: Lateral Soil Salinity Gradients around Roots”; and “Improving Crop Production on Saline Soils in Arid Regions: Do We Need a Different Approach to Develop and Select Plants for These Regions?”

The important subject of beneficial aspects of stress, which has received very little attention, is covered in Part X. This part consists of a unique chapter entitled “Salinity-Induced Enhancement of Horticultural Crop Quality,” which presents available information on this subject.

Numerous figures and tables have been provided in this book to facilitate the comprehension of the materials that have been presented. An extensive index has also been generated to further increase accessibility to the desired information.

**Mohammad Pessarakli**

# Acknowledgments

I would like to express my appreciation for the assistance that I received from the secretarial and administrative staff of the School of Plant Sciences, College of Agriculture and Life Sciences, the University of Arizona, Tucson, Arizona. The continuous encouragement and support of the school Director, Dr. Kenneth Feldmann, and the school Associate Director, Dr. Dennis T. Ray, for my editorial work, especially the books, is always greatly appreciated. Dr. Feldmann and Dr. Ray, your encouraging words have certainly been a driving force for the successful completion of this project.

In addition, I would like to express my sincere gratitude to John Sulzycki (senior editor, Taylor & Francis Group, CRC Press) who supported this project and my previous book projects from their initiation to their completion.

My sincere acknowledgments also to Randy Brehm (editor, Taylor & Francis Group, CRC Press), whose professionalism, patience, proactiveness, and hard work were instrumental in the completion of this project. This job would certainly not have been completed as smoothly and rapidly without Randy's valuable support and sincere efforts.

I am also indebted to Jill Jurgensen, senior project coordinator, for the professional and careful handling of the book. Jill, many thanks to you for your extraordinary patience and thoroughness in handling this huge book as well as my previous book projects. Also, the sincere efforts and the hard work of the copy editor and the acquisition editor can never be forgotten.

The collective sincere efforts and invaluable contributions of several competent scientists, specialists, and experts in the field of plant/crop stress made it possible to produce this unique source for those seeking information on this subject. Each and every one of these contributors and their contributions are greatly appreciated.

Last but not least, I thank my wife, Vinca, a high school science teacher, and my son, Mahdi, a fourth-year medical college student, who supported me during the course of this project.

---

# Editor

**Dr. Mohammad Pessarakli** is a research associate professor and a teaching faculty member in the School of Plant Sciences, College of Agriculture and Life Sciences, the University of Arizona, Tucson, Arizona and senior lecturer in the Department of Plant Sciences, College of Agriculture and Life Sciences, the University of Arizona. He received his BS (1977) in environmental resources in agriculture and his MS (1978) in soil management and crop production from Arizona State University, Tempe, Arizona, and his PhD (1981) in soil and water science from the University of Arizona, Tucson, Arizona. Tucson, Arizona.

His work at the University of Arizona includes research and extension services as well as teaching courses in turfgrass science, management, and stress physiology. He is the editor of the *Handbook of Plant and Crop Stress* and the *Handbook of Plant and Crop Physiology* (both titles published by the Taylor & Francis Group, CRC Press), and the *Handbook of Photosynthesis* and the *Handbook of Turfgrass Management and Physiology* also published by Taylor & Francis Group, CRC Press. He has written 13 book chapters, is an editorial board member of the *Journal of Plant Nutrition and Communications in Soil Science and Plant Analysis* and the *Journal of Agricultural Technology*, a member of the Book Review Committee of the Crop Science Society of America, and a reviewer for *Crop Science*, *Agronomy*, *Soil Science Society of America*, and *HortScience*. He is also the author or coauthor of nearly 90 journal articles.

Dr. Pessarakli is an active member of the Agronomy Society of America, Crop Science Society of America, and Soil Science Society of America, among others. He is an executive board member of the American Association of the University Professors (AAUP), Arizona Chapter. He is a well-known, internationally recognized scientist and scholar and an esteemed member (invited) of *Sterling Who's Who*, *Marques Who's Who*, *Strathmore Who's Who*, *Madison Who's Who*, and *Continental Who's Who*, as well as numerous honor societies (i.e., Phi Kappa Phi, Gamma Sigma Delta, Pi Lambda Theta, Alpha Alpha Chapter). He is a certified professional agronomist and a certified professional soil scientist (CPAg/SS) designated by the American Registry of the Certified Professionals in Agronomy, Crop Science, and Soil Science. He is also a United Nations consultant on agriculture for underdeveloped countries. His research work on environmental stress and his expertise on plants and crops is internationally recognized.

For more information on Dr. Pessarakli, please visit <http://ag.arizona.edu/pls/faculty/pessarakli.htm>

## 1.1 INTRODUCTION

Soil salinity and sodicity are among the major agricultural problems limiting plant growth and development throughout the world [2,6–8,10,12–18,22,23,26,29,30,32–35,40,42,48–52,54,59–63,66,67,71–74,80,83–86,100,105–107,109,110,112,114,115,121–124,132–134,136–144,149–152]. Salinity and sodicity problems in agriculture have an ancient history, and presently have become a very cumbersome problem in agricultural and farming activities [153]. These problems are especially of great concern for countries that their economies rely to a great extent on agriculture.

Salinity and sodicity problems are common in arid and semiarid regions, where rainfall is insufficient to leach salts and excess sodium ions out of the rhizosphere. In addition, these areas often have high evaporation rates, which can encourage increase in salt concentration at the soil surface. The arid and semiarid regions include almost one-third of the world's land [80,108,114]. According to the Food and Agricultural Organization (FAO) [46] of the United Nations, total salt-affected area of the world has been estimated to be over 800 million ha.

The presence of a cliche horizon and/or a cemented hardpan layer at varying depths plus insufficient precipitation for leaching often adds to the salt accumulation in these soils.

Newly established irrigation projects, with improper planning and management practices, may also add salts to soils [88].

Soil salinity and sodicity problems are present in nearly every irrigated area of the world and also occur on nonirrigated croplands and rangelands. Thus, virtually no land is immune to salinization. Therefore, for sustaining life on earth, control of these problems and finding new ways to utilize these extensive saline and sodic soils and water resources, at least for agricultural purposes, are vital and urgent. Reclamation, or at least minimizing the effect of salinity and/or sodicity, is important

---

<sup>†</sup> Deceased.

and necessary. In this respect, proper utilization of water for both plant growth and soil salinity and sodicity control is probably of the greatest importance.

The main focus of this introductory chapter is to summarize general information on salt-affected (saline and sodic) soils, factors influencing their formation and reclamation, and discussing salinity and sodicity as plant/crop stress factors.

## 1.2 SIGNIFICANCE OF SOILS IN RESPECT OF CROP STRESS

As far as all the crops are grown on soils, soil properties have substantial influence on the life conditions of plants and crops. In nature, usually particular plant species grow on specific soils. Thus, specific relationships exist between a particular soil and the vegetation cover of that specific soil. For example, Kreeb et al. [68] investigated soil and vegetation relationships associated with sodic-saline soil surfaces.

Plant development and successful crop production require proper soil conditions, including adequate water and nutrient supply. Unfavorable soil conditions, environmental stress [2,31,130,135], salinity and/or sodicity [6–8,13,14,18,22,25,26,29,34,40,51,54,60,62,66,71,83,85,91–94, 96,97,115,124,132,133,136,137,139–142,148,149,151], and inadequate nutrient supply [98,145] have an adverse effect on the life of the plants, sometimes seriously hindering their effective production.

Based on the above facts, we can speak of stress factors originating in the soil, i.e., such unfavorable soil conditions which cause, or contribute to, the stress factors plants and crops are exposed to.

It is impossible to list all or most of such factors in a short introductory chapter. Therefore, the authors limit the range of this chapter to a general description of soil behavior and its function in nature and production as well as to an outline of one of the most serious factors originating salt-affected soils. For more in-depth information regarding salt-affected soils, the readers are referred to more comprehensive available sources [9,21,24,27,37,41,43,69,77–79,82,87,97,106,113,119,125,128,129,146,147].

## 1.3 PLACE AND ROLE OF THE SOIL IN NATURE

It is generally accepted that the soil is a substantial part of the environment, comprising different substances and forming a special kind of ecosystem inside the given ecosystem, with various properties and attributes. It is also accepted that the soil of the continents is of high diversity, which is dealt with by several branches of soil science, e.g., taxonomy, classification, survey, mapping, etc.

The soil, or the pedosphere, which is an environmental synonym of the soils of a given territory, has a specific place in nature. It is a natural body, similar to rocks, waters, or biota, in the sense that they too have their own materials, mass and energy fluxes, development, and regularities. This fact should be mentioned because, not only in newspapers but also in technical literature, soils are frequently treated either as living substances or as nonbiological substances. Neither of these approaches is correct, because one of the characteristics of the soil is its complexity, the fact that it contains both living and nonliving substances, forming due to both biotic and abiotic processes.

The soil as a natural body is inseparable from the rocks and the crust of weathering on the surface of the continents from which it has developed, on the one hand, and from the biological processes on the other hand. The main characteristics that distinguish the soil from the rocks is the result of biological processes: the production of organic matters by the activities of microorganisms, plants, invertebrates, and other animals, and, finally, human beings, which transforms the rocks into soils, capable of supplying plants and crops with nutrients and water, and being an anchor for their establishment and stands on the land.

The processes of soil formation started concurrently with the appearance of life on the continents and continued during the billions of years of interactions between living substances and rocks under the influence of climatic conditions, with particular regard to the action of water, vegetation cover, organism (both macro and micro), geomorphological patterns, and the time factor. As a result of their interactions, specific mass and energy fluxes formed the different soil types in various environmental conditions.

**FIGURE 1.1** Schematic diagram of the interaction of lithosphere, atmosphere, biosphere, hydrosphere, ecosystems, and soils. (From Szabolcs, I., *Salt-Affected Soils*, CRC Press, Boca Raton, FL, 1989.)

With the appearance of the human race on the face of the earth, even changes in the environment became different. Due to human activities, the natural processes affected by biotic and abiotic factors accelerated, and several others that were unknown or minimal before developed.

The role of soils in nature is complex and multisided, including biospheric, hydrospheric, and lithospheric functions. Their interaction is illustrated in Figure 1.1 [128]. Figure 1.1 clearly shows that the soil is a specific body related to the ecosystem. Even the word “soil” is very often used as a synonym of ecosystem when characterizing the given ecological conditions in a certain place. If we want to be precise, we must agree that the ecosystem includes the pedon, in other words, the soils. However, the soil includes different phases (solid, liquid, gaseous), living and nonliving substances, plants, animals, microbes, and has its own energy and material fluxes. Therefore, it can be considered an ecosystem in itself. In this respect, when speaking of soils versus their plant cover, we can consider the soils of a given location as the basis, ladder, and foothold, for instance, that in savannas or in the tropical belt, a well-defined plant cover develops and very often the soil properties promote or limit the living conditions of certain plant species or associations.

Based upon the above considerations, it can be accepted that certain soil types, when discussed as the habitat for certain plant associations, are often named as the ecosystem of the plant association concerned, as the pedon includes, apart from the plants, most of the components of the ecosystem.

Evidently, the soil, as a specific natural entity, is far from being identical with the vegetation, and, in spite of their close correlation, direct conversion between soil types and vegetation is hardly possible. Still there are soil types that, more or less, determine the ecological function for certain types of vegetation either by providing beneficial conditions for their development or by limiting the ecological conditions for other types of vegetation.

This is perhaps best demonstrated in the case of salt-affected soils where high electrolyte contents of extreme pH conditions limit the development of the majority of plants and serve as a habitat only for such species that can survive or tolerate the unfavorable conditions caused by the salinity and sodicity of the soil. For example, the grass *Leptochloa fusca* that grows vigorously on the salt-affected soils can tolerate extremely saline and sodic (alkaline) conditions [69]. This species is also well adapted to the waterlogging encountered on saline and sodic (alkaline) soils. Saltgrass (*Distichlis spicata*) is another example of a highly salt-tolerant plant species that grows vigorously on saline and sodic soils [76,89–92,94–96]. In fact, the intensive investigations of the senior author

of this chapter and his coworkers on this plant species have found that this grass performed better than control when some salt was added to it during its establishment period, and so far it has been the most salt- and drought-tolerant species compared to the other highly salt-tolerant halophytes that have been tested by this investigator [89,90,94]. Other investigators [39,68,97,111] have also reported on the soil and vegetation relationships that specific plant types are adapted and growing on specific habitats. In such respects, salt-affected soils can be considered as habitat or ecosystems for halophytes, and, if we agree on this, correlations can be found between the different types of salt-affected soils and their flora and fauna as components of the ecosystem.

In order to cast light on both the theoretical and practical aspects of such considerations, it is necessary to describe briefly the properties and grouping of salt-affected soils with regard to the possibilities of the occurrence and distribution of halophytes and xerophytes developing on them.

1.4 EXTENSION AND GLOBAL DISTRIBUTION OF SALT-AFFECTED SOILS

Nearly 10% of the total land surface is covered with different types of salt-affected soils. Table 1.1 demonstrates the distribution of salt-affected soils in the world [65]. Table 1.1 shows that no continent on our globe is free from salt-affected soils. They are distributed not only in deserts and semidesert

TABLE 1.1  
Salt-Affected Soils on the Continents  
and Subcontinents

| Continent                  | Area (Millions ha) |
|----------------------------|--------------------|
| North America              | 15.7               |

| Europe                     | 50.8               |
| Total                      | 954.8              |

FIGURE 1.2 Global distribution of the salt-affected soils.

regions, but also frequently occur in fertile alluvial plains, river valleys, and coastal areas, close to densely populated areas and irrigation systems [27,37,41,45,46,78,87,108,112,128,129].

Figure 1.2 shows the distribution of salt-affected soils throughout the world [129].

## 1.5 DEVELOPMENT AND GROUPING OF SALT-AFFECTED SOILS, PARTICULAR PLANT/CROP GROWTH STRESS FACTORS

In spite of the fact that the properties and attributes of salt-affected soils have been well known for a long time, it is appropriate to give a brief definition of this group of soils right at the start, because the salinity and sodicity (alkalinity) as well as the acidity of soils are substantial stress factors, seriously affecting the productivity of the land [2,7,8,10,12–18,22,23,25,26, 28–33,35,36,40,42, 48–52,54,56,59–63,67,70–74,80,83–87,98–100,105–107,109,110,112,114,115,121–124, 128–130,132–133,143–145,148–150,153].

Salt-affected (i.e., saline, saline-sodic, and sodic) soils usually have low biological activity both because of osmotic and ionic effects of salts and due to limitation of carbonaceous substrates. Rao and Pathak [103] reported that microbial growth was depressed in sodic (alkali) soils due to, at least in part, limitation in carbon substrate (carbon stress), and in saline soils due to salt stress.

For detailed information on the formation of salt-affected soils, the readers are referred to Szabolcs [128,129] and Pessarakli [87].

Salt-affected soils can be characterized as soils formed under the dominant influence of different salts in their solid or liquid phases, which will then have a decisive influence on the development, characteristics, physical, chemical, and biological properties, and eventually the fertility of the soil. Whenever and wherever this phenomenon occurs, it produces specific formations of soils where the high electrolyte concentration and its consequences overshadow the former soil-forming processes or former soil properties and environmental conditions, often radically changing them.

High electrolyte concentration is the only common feature of all salt-affected soils. Their chemistry, morphology, pH, and many other properties may be different, depending on the character of salinization and/or alkalization.

Salt-affected soils, in the broader sense, can be divided into the following groups:

1. Saline soils that develop under the influence of electrolytes of sodium salts with nearly neutral reaction [dominantly sodium sulfate ( $\text{Na}_2\text{SO}_4$ ), sodium chloride ( $\text{NaCl}$ ), and seldom sodium nitrate ( $\text{NaNO}_3$ )]. These soils occur mainly in arid and semiarid regions and form a major part of all the salt-affected soils of the world.

High contents of soluble salts accumulated in these soils can significantly decrease their value and productivity.

2. Sodic (alkali) soils that develop under the influence of electrolytes capable of alkaline hydrolysis [mainly sodium carbonate ( $\text{Na}_2\text{CO}_3$ ) and sodium bicarbonate ( $\text{NaHCO}_3$ ) and seldom sodium silicate ( $\text{Na}_2\text{SiO}_3$ ) and sodium bisilicate ( $\text{NaHSiO}_3$ )]. This group is well extended in practically all the climatic regions from the humid tropics to beyond the polar circles, and their total salt content is usually lower than that of saline soils, sometimes even strongly sodic (alkaline).

Virgin sodic (alkali) soils have a high pH and high exchangeable sodium (Na) percentage (ESP) and are often barren.

Sodic soils exhibit poor physical conditions that adversely influence water and air movement in the soils. Sodicty causes soil erodibility and impairs plant growth [82,87].

3. Salt-affected soils that mostly develop owing to the presence of calcium sulfate ( $\text{CaSO}_4$ ) [gypsiferous soils] or, rarely, in the presence of calcium chloride ( $\text{CaCl}_2$ ). Gypsiferous soils can mainly be found in the arid and semiarid regions of North America, North Africa, the Near East, Middle East, and Far East, and also in Australia.

4. Salt-affected soils that develop under the influence of magnesium salts. This group occurs in arid, semiarid, and even semi-humid regions, and has a particular significance, especially those soils that have a heavy texture.
5. Acid-sulfate soils whose salt content is composed mainly of  $\text{Al}_2(\text{SO}_4)_3$  and  $\text{Fe}_2(\text{SO}_4)_3$ . This type of salt-affected soils is broadly extended in the tidal marsh areas along the seashores of all the continents. These soils are particularly common in North Europe, the western and eastern coastlines of Africa, along the coastline of South-East India, and develop on sulfurous marine sediments.

Inland acid-sulfate soils can also be found in different areas of the world, such as the western territories of the United States, Asia Minor, and China. Such soils develop as a result of fluvial glacial processes and have had no connection with seashores in recent geological times.

Evidently, the different groups of salt-affected soils have diverse physicochemical and biological properties besides the one they have in common, i.e., a comparatively high electrolyte content.

The grouping of the salt-affected soils and their properties causing plant and crop stress are presented in Table 1.2.

The five groups in Table 1.2 represent the formations of different salt-affected soils described above, indicating their chemical types, the environmental conditions where they dominate or occur, the pattern of their main adverse effect on production, and the basic methods of their reclamation. For detailed information on formation and reclamation of salt-affected soils, see Szabolcs [128,129] and Pessarakli [87].

In Table 1.2, the adverse properties of different salt-affected soils causing crop stress are also included. From these, it is clear that, in various groups, different properties are responsible for hindering the development of plants and crops by causing stress.

In saline soils, it is the high salt concentration in the solid and liquid phases that results in high osmotic pressure, hindering the normal development of plants, the stress factor is the salinity with

**TABLE 1.2**  
**Grouping of Salt-Affected Soils and Their Properties Causing Plant and Crop Stress**

| Types of Salt-Affected Soils | Electrolyte(s) Causing Salinity and/or Sodidity        | Environment                                                                                            | Properties Causing Plant and Crop Stress                          | Methods for Reclamation                                     |
|------------------------------|--------------------------------------------------------|--------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------|-------------------------------------------------------------|
| Saline                       | Sodium chloride and sulfate (in extreme cases nitrate) | Arid and semiarid                                                                                      | High osmotic pressure of soil solution, toxic effect of chlorides | Removal of excess salt (leaching)                           |
| Sodic                        | Sodium ions capable of alkaline hydrolysis             | Semiarid, semi-humid, and humid                                                                        | High (alkali) pH, poor water physical conditions                  | Lowering of neutralizing the high pH by chemical amendments |
| Magnesium                    | Magnesium ions                                         | Semiarid and semi-humid                                                                                | Toxic effect, high osmotic pressure, Ca deficiency                | Chemical amendments, leaching                               |
| Gypsiferous                  | Calcium ions (mainly $\text{CaSO}_4$ )                 | Semiarid and arid                                                                                      | Low (acidic) pH toxic effect                                      | Alkaline amendments                                         |
| Acid sulfate                 | Ferric and aluminum ions (mainly sulfates)             | Seashores and lagoons with heavy, sulfate-containing sediments, diluvial inland slopes and depressions | High acidity and the toxic effect of aluminum                     | Liming                                                      |

all its disadvantageous consequences of plant life. Apart from this, some compounds of the salt content of these soils, e.g., chlorides as toxic elements, also act as one of the stress factors.

In sodic (alkali) soils, as a rule, not the high salt concentration but the sodic (alkaline) pH value is the stress factor, particularly in cases where there is a high concentration of sodium carbonate in the solid and liquid phases of the soil. The high pH hinders the life function of crops and limits their development.

In another group of sodic (alkali) soils, which sometimes does not have very alkaline pH value (solonetz type), the comparatively low concentration of sodium salts capable of sodic (alkaline) hydrolysis constitutes a stress factor through its action, resulting in poor water physical properties in the soil. As a consequence of this phenomenon, the wilting point in the soil increases and the plants suffer from water deficiency, even in wet soils, due to the swelling of clay saturated with sodium ions ( $\text{Na}^+$ ).

In magnesium soils, which have not been adequately studied, the combination of toxic effect, calcium deficiency, and poor soil physical properties are the stress factors.

In gypsiferous soils, the acidic pH and sometimes the toxic effect of the high gypsum content, contribute to the appearance of stress factors for plant and crop life in areas with large extensions of intensively gypsiferous soils.

In acid-sulfate soils, the very high acidity, with a pH sometimes below 2, poses stress with all the adverse effects of extreme acidity. Furthermore, the high aluminum content of the soil solution has an intensive toxic effect.

Apart from this, the temporary or permanent waterlogging in such soils acts as a stress factor, hindering the normal air and nutrient regime, necessary for plant life, in these soils.

Besides the salt-affected soils developing due to natural soil-forming processes, the so-called secondary salt-affected soils have an increasing importance that is both scientific and practical. Secondary salt-affected soils are those that have been salinized due to man-made factors, mainly as a consequence of improper methods of irrigation. The extension of secondary salt-affected soils is rather sizeable, and this adverse process is as old as irrigated agriculture itself. Old civilization in Mesopotamia, China, and Pre-Columbian America fell in consequence of the salinization of irrigated land. The process is also advancing vigorously at present and more than half of all the irrigated lands in the world are under the influence of secondary salinization and/or alkalization.

When speaking of the man-made factors of salinization, we also have to mention potential salt-affected soils that are not salt-affected at present, but in case of the extension of irrigation, deforestation, overgrazing, and other man-made measures, can and will be salinized unless the necessary preventive procedures are undertaken in due time. No global records are available of the size of potential salt-affected soils; however, the area that they cover is larger than that of existing salt-affected soils.

Secondary salt-affected soils can be divided into the following two categories:

1. Secondary formation of salt-affected soils caused by irrigation.

In spite of the negative experiences, the salinization of irrigated and surrounding areas has not diminished. On the contrary, it is still on the increase.

According to the estimates of the FAO and UNESCO (the United Nations' Educational, Scientific and Cultural Organization), as much as half of all the existing irrigation systems of the world are, more or less, under the influence of secondary salinization, alkalization, and waterlogging. This phenomenon is very common not only in old irrigation systems but also in areas where irrigation has only recently begun.

According to the estimates of the above mentioned agencies, 10 million ha of irrigated land are abandoned yearly because of the adverse effects of salinity due to irrigation, mainly secondary salinization and alkalization.

The mentioned losses and damages are not evenly distributed among the irrigating countries. In some of them, the damage may be relatively small, while in others it actually constitutes the major problem in agriculture or even in the national economy of the country in question. In this respect, unfortunately, there are countless sad examples.

In Pakistan, Ahmad [4] carried out statistical analyses in respect of secondary salinized land. According to his data, out of 35 million ac (approximately 16 million ha) of total irrigated territory, salinized areas account for 5.3 million ac (approximately 2.4 million ha) after a few years of irrigation. He indicated among the causes of secondary salinization in Pakistan the joint effect of irrigation and ground water. According to Zavaleta [147], practically all irrigated alluvial soils in Peru show the features of salinity and sodicity (alkalinity). It is known from FAO reports [45,46] and the papers of Kovda [64] that more than 40% of irrigated soils in Iraq and Iran are affected by secondary salinization. A country report by FAO [45] on salinity in Syria estimated the adverse effects of salinity as follows:

- a. In more than 20,000 ha, salinity developed to a level where these soils had to be taken out of cultivation, and the loss is estimated at a total of 30,000 ton of cotton per year.
- b. In about 30,000 ha, the yield decreased by 50% and the total loss is estimated at 20,000 ton of cotton per year.
- c. In about 60,000 ha, the yield decreased by 20%, and the total loss is estimated at about 18,000 ton of cotton per year.

At present, no continent is free from the occurrence of this very serious phenomenon. In Argentina, 50% of the 40,000 ha of land irrigated in the nineteenth century are now salinized. In Australia, secondary salinization and alkalization take place in the valley of the river Murray, and in Northern Victoria 80,000 ha have been affected. The same phenomena can be observed in Alberta, Canada, and similar processes have been recorded in the northern states of the United States, where irrigation was introduced much later than in the dry west. It is noteworthy that these last examples, and many other irrigated regions, are far from being arid areas and the majority of salt accumulations are associated with the sodium salts capable of sodic (alkaline) hydrolysis, and not with the neutral sodium salts that we are familiar with in desert and semidesert areas.

The more recent reports of the FAO [46] of the United Nations estimated the salt-affected areas due to irrigation in the developing countries, including the above mentioned ones (Iran, Iraq, Pakistan, and Syria) much higher than the previous reports.

2. Secondary formation of salt-affected soils caused by human activities other than irrigation. When speaking of secondary salinization, most people think of irrigation and drainage. However, there are also other anthropogenic factors causing this adverse phenomenon. It is true that the majority of secondary salt-affected soils develop as a result of improper methods of irrigation, but there are other human effects that more and more often trigger this process in many places, both in arid and humid areas.

Some of these anthropogenic processes are, including but not limited to, the following:

- a. Overgrazing

This process occurs mainly in arid and semiarid regions, where the natural soil cover is poor and scarcely satisfies the fodder requirement of rather extensive animal husbandry. If, due to overgrazing, the natural vegetation is sparse or annihilated, progressive salinization develops and, step by step, the scarcity of the plant cover becomes increasingly pronounced. Sometimes, the process ends in desertification because even the poor pasture diminishes and no other fodder resources are available. According to Theunissen [131], the gradual decline in the ecological condition of natural pastures as a result of overgrazing and the application of insufficient management decisions, coupled with the detrimental effects of long-term drought, has left extensive areas of high potential grazing land in southern Africa in urgent need of restoration. However, due to the limited number of grasses currently available for rehabilitating and restoring the vast number of different habitats encountered, selecting indigenous grasses suitable for restoration of denuded areas in the arid and semiarid grasslands of Southern Africa was initiated.

b. Deforestation in semi-humid and semiarid areas

Particularly, in the last few decades, it has become evident that deforestation results in many tropical and subtropical countries in the salinization and alkalization of soils due to the effects of soil migration both in the upper and the lower layers. In South East India, e.g., vast territories of former forest land became intensely saline and sodic (alkaline) in a few years after the annihilation of the woods. Similar phenomena occurred in the forest steppe areas in Russia, Iran, East-Central Europe, and Latin America.

c. Salinization caused by contamination with chemicals

In spite of the fact that the amount of chemicals applied in agriculture is practically negligible, in comparison to the salt content of several soils, we have considered the fact that this kind of salinization more and more often occurs in modern intensive agricultural production, particularly in greenhouses and intensive farming systems. When production takes place in semi-closed systems (e.g., greenhouses), where the chemicals applied will not be removed regularly, the accumulation of salts or their components becomes possible in the upper layer of the soil, resulting in salinity and sodicity (alkalinity). In Japan, the Netherlands, and other countries with intensive agriculture, and particularly horticulture, such type of salinization more and more frequently appears, causing serious losses of crop yields.

d. The accumulation of airborne or waterborne salts

Due to the concentration of industrial plants, the emission of chemical compounds may accumulate in the soil and, if their concentration is high enough, they result in salt accumulation in the upper layer of the soil.

A similar phenomenon appears when, due to water system regulations, sludge water disposal, and other hydrotechnical measures, water with considerable salt concentration contaminates the upper soil layer, causing salinization and/or alkalization.

## 1.6 RECLAMATION OF SALT-AFFECTED SOILS, RELIEVE OR ELIMINATION OF PARTICULAR PLANT/CROP STRESS FACTORS

The major environmental stresses caused by soil salinity and sodicity have existed long before the agricultural practices have started. Soil salinity and sodicity have a substantial effect in reducing agricultural production worldwide [2,6–8,10,12–20,22,23,26,29,30,32–35,40,42,48–52,54,59–63,66,67,71–73,80,83–86,100,105,107,109,110,112,114,115,121–124,132–134,136–144,148–150,152]. This has a major impact on increased food and feed insecurity globally, particularly in developing countries that are more prone and vulnerable to salinization and desertification due to lack of advanced technology, adequate education, and other socioeconomical and technological problems. Population growth and increasing demand for food and agricultural products necessitate using the salt-affected soils and marginal lands for food production. These soils are needed for the agricultural extension and, hence, reclamation is required. Reclamation is needed on the millions of hectares of slowly permeable salt-affected (i.e., saline–sodic and sodic) soils throughout the world [2,46,55,63,87,112,124,150].

Different techniques of reclamation and preventive measures or management practices are used for reclamation of salt-affected soils and reducing the salt contents of the growth medium or to find more stress-tolerant plant/crop species and cultivars via genetic engineering to combat salinity stress. These management practices were aimed to enable plants to grow in saline and sodic conditions to utilize salt-affected soils for agricultural practices and food production [2,3,5,10,12,15–20,23,28,30,32,33,35,38,42,44,47–49,52,56,59,61,63,69,72,80,81,84,86,87,99,100,105,107–110,114,117–119,121–124,126,131,134,138,143,144,149,150,152]. Saline soils are usually reclaimed by leaching the salts out of the soil through irrigation and drainage systems, whereas reclamation of sodic (alkaline) soils requires application of chemical amendments followed by the leaching process.

Present recommendations for reclamation of the salt-affected soils are usually based only on relatively simple and often empirical relations. Various amendments and management strategies have been used for reclamation of the salt-affected soils. To evaluate particular reclamation strategies, some specific considerations should be noted as follows:

1. The quantity of water needed
2. The quality of water needed
3. The quantity of amendments to be used
4. The type(s) of amendment(s) to be used
5. The time required for reclamation to be completed

Chemical reactions such as cation exchange, precipitation, and dissolution of solid phases (reclamation amendments) and the soil hydraulic properties and corresponding changes in the water flow and solute transport rates must be considered [119].

Among the various reclamation practices, usually, a combination of added gypsum amendment and crop rotation has been proven the best.

Reclamations of salt-affected (saline-sodic and sodic) soils by chemical amendments has become cost-intensive and requires high capital investment, and are not always a practical solution to the problem of soil salinity and sodicity. Therefore, biotic approach such as cultivation of salinity- and sodicity-tolerant plants and crops on salt-affected soils, i.e., “saline agriculture,” may be another alternative.

Cultivation of different salinity- and sodicity-tolerant plant types and species have been used by several investigators, i.e., grasses [44,62,69,75,76,89–91,93–97,99,131,140,148], agronomic crops [5,15,16,19,20,23,42,47,48,61,63,72,73,81,86,108,114,121–123,149,150], forest species, and trees [10,28,54,117,118,126] for reclamation purposes. These plants can mobilize the native lime (calcium carbonate,  $\text{CaCO}_3$ ) in these soils through root action, a substitute for the chemical approach. Qadir et al. [97], studying the combination of chemical amendments and biological (using plants) reclamation technique, reported that the soil treated with gypsum at a high rate (100% GR, grade reagent) removed the greatest amount of  $\text{Na}^+$  from the soil columns and resulted in a marked decrease in soil salinity (EC, electrical conductivity) and sodicity, sodium absorption ratio (SAR), and ESP (exchange sodium percentage). The performance of grass treatment in enhancing the leaching of  $\text{Na}^+$  was between the gypsum treatments.

According to Kumar [69] and Qadir [97], the grass, *Leptochloa fusca*, was very useful and effective in the reclamation of salt-affected soils. This plant can tolerate extremely saline and sodic (alkaline) conditions. Since its growth is not affected by gypsum application, planting with *Leptochloa* is an alternative biological rather than a chemical method for the reclamation of sodic (alkaline) soils. This plant is also well adapted to the waterlogging encountered on saline and sodic (alkaline) soils. The plant improves the soil's physical, chemical, and biological properties so that within 2 or 3 years many commercial and forage crops can be grown on the soil [69]. *Leptochloa* excretes salts through specialized glands and is, therefore, reasonably palatable to farm animals. It must be noted that because of its vigorous growth on sodic (alkaline) soils, *Leptochloa* does not allow satisfactory growth of companion plant species, especially in the initial years of soil reclamation.

Subramaniam and Babu [126] also used a forest shrub species for reclamation of sodic soils. According to these investigators [126], *Sophora mollis*, which is a shrub to medium-sized tree and is used for both fodder and firewood, can be used in the reclamation of sodic (alkaline) soils.

Kilic et al. [63] investigated the salt-removing capacity of purslane (*Portulaca oleracea* L.) by studying different stress criteria and by tracking its salt removal from germination to harvest. The results of their study showed that purslane could cumulatively remove considerable amounts of salt from the soil if practical to cultivate as an intercrop all year round.

Saltgrass (*Distichlis spicata*) that has been found the only vegetation cover on a highly sodic (alkaline) soil in Wilcox Playa, Arizona [92] can also be very effective in reclamation of saline

and sodic soils. As mentioned earlier, the senior author of this chapter and his coworkers found this grass to be very high salt-tolerant plant species that grows vigorously on saline and sodic soils [76,89–92,94–96]. Compared to the other highly salt-tolerant halophytes that have been tested by this investigator [89,90,94], so far, this grass has proven the most salt and drought tolerant of all the tested species.

Although slow, definite improvement is achieved in the physicochemical properties of the salt-affected soils by encouraging the vegetation growth on such lands. The tree species in general are effective in improving the soil properties as reflected by the changes in physicochemical characteristics of the soil such as bulk density (BD), water holding capacity (WHC), hydraulic conductivity (HC) and pH, EC, OC (organic carbon), N (nitrogen) and exchangeable cations ( $\text{Na}^+$  and  $\text{Ca}^{++}$ ) [117].

Due to the low biological activity and depressed microbial growth of salt-affected (i.e., saline, saline–sodic, and sodic) soils, there is a need for applying organic amendments (i.e., plant residue or manure) during sodic (alkali) soil reclamation. In reclamation of saline soils, organic amendments must be applied following the leaching process.

Kumar et al. [70] conducted a combination of biological and chemical reclamation study on a highly sodic (alkaline) soil. These investigators [70] found that rice produced satisfactory yields in the first year of gypsum application, but sorghum and *Sesbania* yields were very poor. The yield of *Leptochloa* was not affected by gypsum application. In their crop rotation practice, Kumar et al. [70] reported that the green forage yield of sorghum was greatest when sorghum followed *Leptochloa* grown for 2 years and the harvested grass was left to be decomposed on the site.

In a biological reclamation study of saline soils, Helalia et al. [53] reported that amshot grass significantly reduced the soil salinity compared to either ponding or gypsum application, and this grass produced a higher fresh yield than clover cultivated in such soils.

The above findings indicate that biological reclamation with the salinity- or sodicty-tolerant plants (i.e., *Leptochloa*, grasses, shrubs, or trees) is a proper substitute for chemical reclamation with gypsum, and the former has an economic advantage over the latter.

Yildirim et al. [144] evaluated the effects of selected biological treatment on direct seeded and transplanted squash plant growth and mineral contents under salinity stress. These investigators reported that salinity negatively affected growth of squash; however, biological treatments significantly increased fresh weight compared to nontreated plants that were under salt stress. They also found biological treatments increased the uptake of potassium compared to the nontreated control in both direct seeded and transplanted squash. Based on their results, these investigators concluded that alteration of mineral uptake may be one mechanism for the alleviation of salt stress, and the use of biological treatments may provide a means of facilitating plant growth under salt stress conditions.

Compost or any other organic materials is recommended to be used during the reclamation process of the salt-affected soils. The results of a field experiment conducted by Avnimelech et al. [21] verified that compost application improved both physical and chemical conditions of saline and sodic (alkaline) soils. Compost application to such soils is expected to release acids, which would ultimately lead to the replacement of exchangeable sodium by calcium. In addition, compost application would stabilize soil structure and enhance plant growth. These investigators [21] found that the municipal solid waste compost application was equivalent or even superior to the addition of gypsum, the most common amendment used to reclaim sodic (alkaline) soils. This was evident from the substantial increase in crop yields. The combined application of compost and gypsum raised yields to the levels equal to that of the commercial fields.

In a field experiment, Batra et al. [24] compared the microbiological and chemical amelioration of a highly deteriorated sodic (alkaline) soil using two reclamation technologies:

1. Growing Karnal grass (*Leptochloa fusca*) as a first crop with no chemical amendment (biological reclamation)
2. Gypsum application as a chemical amendment for different crop rotations

These investigators [24] reported that the microbiological properties changed more than the chemical properties of sodic (alkali) soil as the time period advanced.

In a biological reclamation study carried out on saline soils, Apte and Thomas [11] found that a brackish water, nitrogen-fixing cyanobacterium, *Anabaena torulosa*, could successfully grow and fix nitrogen on moderately saline soils (EC of 5–8.5 dS m<sup>-1</sup>). These investigators [11] reported that cyanobacterium exhibited high rates of nitrogen fixation and substantially enriched the nitrogen status of saline soils. However, permanent removal of Na<sup>+</sup> from saline soils using cyanobacteria or any other microorganisms may not be possible, since Na<sup>+</sup> is released back into the soil subsequent to the death and decay of cyanobacteria or other microorganisms. Amelioration of soil salinity by simultaneous application of *Anabaena torulosa* during crop growth seems to be an attractive possibility for reclamation, especially since it can also supplement the nitrogen requirement of the crops growing on these soils.

Blue-green algae that tolerate excess Na and grow extensively on the soil surface in wet seasons were found effective in sodic soils reclamation [102]. However, a permanent reclamation of such soils by using only blue-green algae as a biological amendment to achieve sodic (alkali) soil reclamation is neither possible nor comparable with an effective chemical amendment such as gypsum.

In the reclamation process of the saline soils, de Villiers et al. [39] compared different annual and perennial species. Of the six species tested, the perennials seemed to be more effective and better suited for rehabilitation purposes under saline soil conditions.

The type of chemical compound being used also influences the reclamation process of salt-affected soils. Sharma and Upadhyay [116] reported that, among the up-to-date known chemical compounds, cyclohexathiazonium chloride (S-6N-4)-2+Cl<sup>-</sup>2 is the best and the most suitable chemical to reclaim the sodic (alkaline) soil at any pH of the soil.

When good quality water is not available for leaching the salts out of the soil, low-quality water can be used for the initial stages of reclamation. In this regard, Singh and Bajwa [120] studied the effects of gypsum and sodic irrigation on the precipitations of Ca<sup>++</sup> and removal of Na<sup>+</sup> from a sodic soil reclaimed with different levels of gypsum and growth of rice in a greenhouse experiment. Dubey and Mondal [43] also used low-quality saline water in conjunction with organic and inorganic amendments for initial stages of reclamation of sodic soils. Using low-quality water, Joshi and Dhir [58] evaluated the rehabilitation of degraded sodic soils using residual sodium carbonate water (low-quality water) combined with gypsum treatment and found that the combination treatment was effective in lowering the soil SAR (sodium absorption ratio) and improved water infiltration rate. In the first year of gypsum treatment, it was possible to establish the crop. In the second year, moderate productions of wheat (2610 kg ha<sup>-1</sup>) and raga (*Brassica* sp.) (2000 kg ha<sup>-1</sup>) were obtained [58].

Using the most common technique, irrigation water and drainage system, for reclamation of the salt-affected soils, the results of an investigation carried out by Millette et al. [77] demonstrated the ability of fall irrigation to leach salts from the surface soil during a period of low consumptive use, which could lead to reclamation. Long-term monitoring would be required to determine whether a further and permanent decline in salinity could be achieved.

Concerning other reclamation materials and techniques, results of Jones et al. [57] indicate that acid whey is effective in reclaiming sodic soil by lowering ESP, SAR, and pH and by improving infiltration rate. Rao and Leeds Harrison [104] used simulation models for desalinization of a drained two-layered saline soil using surface irrigation for different water management practices to increase leaching efficiency. Based on image elements and their correlation with the ground features, Rao et al. [101] suggested categorizing sodic soils in moderately and strongly sodic groups. The delineation thus made would help the execution of a reclamation program for sodic soils at the study sites. Abdel-Hamid et al. [1] monitored soil salinity in the northern Nile delta Egypt by using data collected via landsat and geographic information system (GIS). The collected data were used in making recommendations for reclamation of the saline soils of the Nile delta area.

The vast area of salt-affected soils still remains a burden for the societies, particularly the undeveloped countries, in need of adequate resources to reclaim them with the available technology

involving initial heavy investments. The process of degradation, which has been due to reckless destruction of vegetation, can be reversed by reestablishment of vegetative cover, which results in slow but definite improvement in such soils. This phenomenon has been demonstrated a great deal by various parameters influencing the soil welfare in several investigations which show a positive sign of improvement both in terms of physical and chemical properties of the salt-affected soils. Such soils should, therefore, be brought under any type of vegetation (i.e., sod, shrub, tree) cover, if not found economical for regular farming and growing agronomic crops, and taken care by the community for posterity [117].

Even by the execution of the reclamation processes, nutrient status and their behavior in salt-affected soils (i.e., saline-sodic and sodic soils) during reclamation by crop rotation and chemical amendments requires a comprehensive assessment. This is because, usually, during the leaching process of the soluble salts and the exchangeable sodium, some soil nutrients are also lost and leached out of the soil. In this regard, several investigators [28,36,98,127,145] have studied nutrient status and behavior during the reclamation processes. Swarup et al. [127] reported the effect of gypsum on the behavior of soil phosphorus during the reclamation of a sodic soil. According to Bhojvaid et al. [28], soil nutrient status under the tree plantation was higher than that of the non-sodic farm soil. This finding confirms that successful tree plantation may restore the productivity and fertility of highly degraded sodic soils.

Regardless, the techniques used in reclamation of salt-affected soils, post-reclamation management practices, i.e., proper choice of crops, crop rotation, method of irrigation, quality and quantity of water used for irrigation and reclamation, fertilization, and the economics of reclamation must be taken into consideration and followed to achieve successful results.

## 1.7 CONCLUDING REMARKS

In this chapter, information has been given on the important functions of the soil in relation to soil-originated stress factors for plant and crop growth and development as well as a little more detailed information of particular problems related to salt-affected soils, their formation and reclamation.

The properties of the stress factors for plant and crop growth originating in soil are diverse and multisided. We know comparatively little about the up-to-date orientation and, particularly, for finding methods to improve the situation and ensure better plant and crop growth and development. Therefore, target-oriented studies of the different kinds of soil-originated stress factors for plant and crop growth and development are necessary so that the complex correlations and actions in the soil-plant-water system can be disclosed with the purpose of a better characterization of stress factors on the one hand, and improving the environmental and production conditions on the other hand.

## 2.1 INTRODUCTION

Arid zones receive inadequate and irregular precipitation to accomplish leaching of salts originally present in the soil profile. Normally when the precipitation is more than 1000 mm per annum, salinity should not develop. This is not the case in arid zones; therefore, salts accumulate in soils. Salt buildup in concentrations detrimental to plant growth is a constant threat in irrigated crop production.

In arid and semiarid regions, evapotranspiration is higher than the total annual rainfall. Therefore, rainfall contributes insignificantly to groundwater recharge, and hence there is a general shortage of fresh quality water to offset the total agriculture water demand in these countries. The shortage of fresh water necessitates the use of marginal quality ground water, such as brackish and saline, for irrigated agriculture. This is highly demanded in water-scarce regions. The improper use of saline/brackish water in irrigated agriculture often introduces salinity and sodicity problems and the soil if not properly managed can reach a condition where it cannot be exploited to its full production capacity. Under such conditions, irrigated agriculture has faced the challenge of sustaining its productivity for centuries, particularly soil and water salinity, poor irrigation, and drainage management continue to plague agriculture especially in arid and semiarid regions (Tanji, 1996).

If soil becomes saline and sodic, it creates plant- and soil-related problems that restrict plant growth through undermining soil quality, and hence many plants either fail to grow in saline soils or their growth is retarded significantly; however, few plants grow well on saline soils (Maas, 1990). Therefore, soil salinity often restricts options for cropping in a given area. Because of this reason, understanding salinity in irrigated agriculture fields is essential for their precise management. Salinity management is highly site specific and depends on factors such as site characteristics, nature of soils, and local hydrological conditions. Soil salinity and sodicity are global issues and not restricted to one country or region.

Once the soil salinity and sodicity are diagnosed and site characteristics are established, integrated management and reclamation strategies specific to the site can be formulated for better results and long-time sustainability of irrigated agriculture.

### 2.1.1 SALINITY AND SODICITY: A GLOBAL SCALE PROBLEM

Planet Earth consists of land surface of about  $13.2 \times 10^9$  ha, out of which only  $7 \times 10^9$  ha are arable and only  $1.5 \times 10^9$  ha are cultivated (Massoud, 1981). Of the cultivated lands, about  $0.34 \times 10^9$  ha (23%) are saline and another  $0.56 \times 10^9$  (37%) are sodic. Older estimates (Szabolcs, 1989) suggest 10% of the total arable land to be affected by salinity and sodicity, and extends over more than 100 countries and almost all continents.

### 2.1.2 SALINITY AND SODICITY

Some people get confused between salinity and sodicity. *Salinity* is a measure of the concentration of all the soluble salts in soil or water. It is expressed as decisiemens per meter ( $\text{dS m}^{-1}$ ) or millisiemens per centimeter ( $\text{mS cm}^{-1}$ ). If we want to keep our soils productive, we need to identify potential salinity problems and be ready with remedies or actions to help reduce the effects or avoid them in the first place. *Sodicity* is a measure of sodium ions in soil or water relative to calcium and magnesium ions (Richards, 1954). It is expressed either as the sodium adsorption ratio (SAR) or as

the exchangeable sodium percentage (ESP). If the SAR of the soil equals or is greater than 13 or ESP equals or is greater than 15, the soil is termed sodic (Richards, 1954).

### 2.1.3 CAUSES OF SALINITY DEVELOPMENT

There may be a number of causes (Plate 2.1) of soil salinity development: (1) inherent soil salinity (parent material); (2) seawater intrusion to coastal areas; (3) uses of brackish/saline water in farming and urban landscapes area; (4) restricted drainage developed into a high water table; (5) low rainfall; and (6) high rate of evapotranspiration. The rainfall contributes 10–200 kg salts per year per ha, depending on the vicinity of the area to the sea or inland.

In farming areas, the continuous pumping of ground water and subsequent use for irrigation purposes (recycling) usually lowers the water table; however, this practice resulted in an increase in water salinity and covert normal soils to become saline with low productivity. These soils need attention for their management and reclamation.

Pumping groundwater to alleviate surface salinity and to lower water table is an effective way, with the condition that ground brackish water is not used directly for irrigation, but with some management, e.g., conjunctive or cyclic use. In areas where water table is high and persistent, the imbalance in the natural water, the clearing of vegetation and the general absence of deep rooted trees, and the absence of adequate drainage cause soil salinity. As the groundwater rises, it brings salt to the surface through capillary rise and subsequent evaporation, which can be harmful to plants by reducing yields. The quality of the groundwater used for irrigation and its rates of recharge are critical too. These considerations make land-water management in irrigated arid lands a delicate task. Subject to these limitations, irrigation helps reduce risks linked to soil moisture stress and enhances yield.

(c)

(d)

**PLATE 2.1** Soil salinization, waterlogging, and plant growth. (a) Patchy salinity in wheat field. (b) Salt accumulation through sea water intrusion—salt flat. (c) Affect of salinity on date palm trees. (d) Waterlogging in forestry field.

The groundwater usually rises 0.6–1.5 m or more in the soil above the water table by capillarity, depending upon texture, structure, and other factors. The water reaching the surface evaporates, leaving a salt-deposit typical of saline soils. Generally, water table below 2 m is considered safe for irrigated agriculture.

### 2.1.3.1 Salinity Development: Hypothetical Cycle

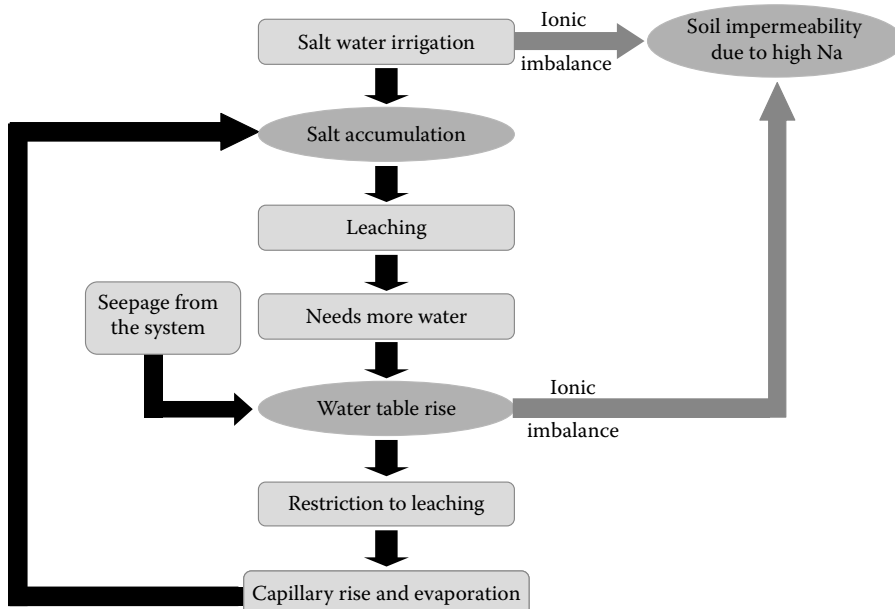

Recently, Shahid et al. (2010) have published a hypothetical salinization development cycle in irrigated agriculture fields (secondary salinization). Figure 2.1 depicts poor irrigation and drainage management and high temperature as the main causes of secondary salinization.

### 2.1.3.2 Dryland Salinity Development

In Australia, dryland salinity is very common and is developed due to clearing of trees to convert the area to arable agriculture. In the former, the rainfall is compensated through high evapotranspiration with no or insignificant leaching; in the latter case, low evapotranspiration relative to former lead the extra rain to leach down and with poor drainage condition, water table developed and subsequent evaporation caused dryland soil salinization.

## 2.1.4 DAMAGE DUE TO SALINITY

An exact estimate of losses caused due to salinity in an area is difficult to know; however, it is clear that losses may be quite considerable, and high cost of work to be done to control salinity must also be added. Different types of salinity damage are; saline water tables can cause productive land to become barren; soil salinity also enhances “erosion” and loss of farm income; salinity can deteriorate the quality of drinking water; in salt-affected areas, roads and building foundations are weakened by high salty water tables and high water table also affects biological activity in the soil.

**FIGURE 2.1** Hypothetical salinization cycle. (From Shahid, S.A. et al., Mapping and monitoring of soil salinization, remote sensing, GIS, modeling, electromagnetic induction and conventional methods—case studies, in *Proceedings of International Conference on Management of Soil and Groundwater Salinization in Arid Regions*, Sultan Qaboos University, Sultanate of Oman, January 11–14, 2010. Volume 1: Keynote papers and Abstracts, pp. 59–97.)

2.1.5 QUICK FACTS ABOUT SALINITY AND PLANT GROWTH

Proper plant selection is one way to moderate yield reductions caused by excessive soil salinity. The stage of plant growth has a direct bearing on salt tolerance. Generally, the more mature the plant, the more tolerant it is to salt. Most fruit trees are more sensitive to salt than are vegetable, field, and forage crops and generally, vegetable crops are more sensitive to salt than are field and forage crops.

2.1.6 INDICATORS OF SOIL SALINIZATION

Once soil salinity is developed in irrigated agriculture fields, it starts showing its effects on soil properties and plant growth. The white salt crust, reduced plant vigor, salt stain on dry soil surface, affected area worsen after rainfall, marked changes in leaf color and shape, and presence of naturally growing halophytes and trees are either dead or dying are the indicators of soil salinity, which can be observed in the field without laboratory analyses.

2.1.7 CLASSES OF SOIL SALINITY AND PLANT GROWTH

Electrical conductivity of the soil saturation extract (ECe) is the standard measure of salinity. Richards (1954) has described general relationship of ECe and plant growth.

| Class                  | ECe (dS m <sup>-1</sup> ) | Plant Growth                                           |
|------------------------|---------------------------|--------------------------------------------------------|
| 0 Nonsaline            | 0–2                       | Salinity effects mostly negligible                     |
| 1 Very slightly saline | 2–4                       | Yields of very sensitive crops may be restricted       |
| 2 Slightly saline      | 4–8                       | Yields of many crops restricted                        |
| 3 Moderately saline    | 8–16                      | Only tolerant crops yield satisfactory                 |
| 4 Strongly saline      | >16                       | Only a few very salt-tolerant crops yield satisfactory |

2.2 CLASSIFICATION OF SALT-AFFECTED SOILS

A soil, which contains sufficient soluble salts in the root-zone to impair the growth of crop plants, is defined as “saline.” However, because salt injury depends on species, variety, growth stage, environmental factors, and nature of the salts, it is very difficult to define a saline soil precisely. The definitions are based on salt content either alone or in conjunction with texture, morphology, or hydrology (Richards, 1954; Northcote and Skene, 1972; FAO-UNESCO, 1974; Soil Science Society of America, 1978). The most widely accepted definition of a saline soil is one that gives an electrical conductivity of extract from saturated soil paste (ECe exceeding 4 dS m<sup>-1</sup> at 25°C), while FAO-UNESCO (1974) mapped soils with ECe exceeding 15 dS m<sup>-1</sup> as strongly saline soils or solonchaks.

2.2.1 U.S. SALINITY LABORATORY STAFF (RICHARDS, 1954) CLASSIFICATION

The term “salt-affected” soil is being used more commonly to include saline, saline-sodic, and sodic soils, which are clearly differentiated by Richards (1954). The term “alkali” to describe soils with excess exchangeable sodium (ES) is being discouraged due to its ambiguity (Overstreet et al., 1951).

*Saline* soils are those which have pHs usually less than 8.5, ECe > 4 dS m<sup>-1</sup> and ESP < 15. The high ECe with low ESP tends to flocculate soil particles into aggregates. The soils are usually recognized by the presence of white salt-crust during some part of the year. Permeability is either greater or equal to those of similar normal soils.

*Saline-sodic* soils contain sufficient soluble salts (ECe > 4 dS m<sup>-1</sup>) to interfere with the growth of most crop plants and sufficient ESP (>15) to affect the soil properties and plant growth adversely by the degradation of soil structure. The pHs may be less or more than 8.5.

*Sodic* soils contain  $\text{ESP} > 15$  and  $\text{ECe} < 4 \text{ dS m}^{-1}$  and pHs generally range between 8.5 and 10 and may even be as high as 11. The low  $\text{ECe}$  and high  $\text{ESP}$  tends to deflocculate soil aggregates and hence lower their permeability.

### 2.2.2 FAO-UNESCO CLASSIFICATION (1974)

Salt-affected soils (halomorphic soils) are also indicated on the soil map of the world (1:5,000,000) by FAO-UNESCO (1974) as solonchaks and solonetz. The origin of both solonchak and solonetz are Russian. Solonchaks are soils with high salinity ( $\text{ECe} > 15 \text{ dS m}^{-1}$ ) within 125 cm of the soil surface. The FAO-UNESCO (1974) divided solonchaks into four mapping units: (1) *orthic solonchaks*—the most common solonchaks; (2) *gleyic solonchaks*—with groundwater influencing the upper 50 cm; (3) *takyric solonchaks*—solonchaks in cracking clay soils and; (4) *mollic solonchaks*—solonchaks with dark colored surface layer, often high in organic matter. Soils with a lower salinity than solonchaks, but higher than  $4 \text{ dS m}^{-1}$  are mapped as “saline phase” of other soil units.

A “solonetz” is a sodium-rich soil that has an  $\text{ESP} > 15$ . The solonetz are subdivided into three mapping units: (1) *orthic solonetz*—the most common solonetz; (2) *gleyic solonetz*—those soils with groundwater influence in the upper 50 cm, and (3) *mollic solonetz*—the soils with a dark colored surface layer, often high in organic matter. Soils with a lower  $\text{ESP}$  than a solonetz, but higher than 6, are mapped as a “sodic phase” of other soil units.

### 2.2.3 USDA: SOIL SURVEY DIVISION STAFF CLASSIFICATION (1993)

The following classes of salinity are used if the  $\text{EC}$  has not been measured, but salinity is inferred (Soil Survey Division Staff, 1993). These are: class 0 (nonsaline,  $0\text{--}2 \text{ dS m}^{-1}$ ); class 1 (very slightly saline,  $2\text{--}4 \text{ dS m}^{-1}$ ), class 2 (slightly saline,  $4\text{--}8 \text{ dS m}^{-1}$ ), class 3 (moderately saline,  $8\text{--}16 \text{ dS m}^{-1}$ ), and class 4 (strongly saline  $\geq 16 \text{ dS m}^{-1}$ ). The class 0 shows no visible salts on the soil surface and plant growth is not affected by salinity/sodicity. In classes 1 and 2, the plant growth may be uneven or patchy. Salts are generally present in small-sized patches (Plate 2.1a), which do not cover more than 25% area collectively. In class 3, the plant growth on these soils is very patchy and the salts are fairly visible on the soil surface. The area in class 4 lies unused and may support some salt-tolerant plants.

### 2.2.4 USDA-NRCS (KEYS TO SOIL TAXONOMY, 2010) CLASSIFICATION

The Keys to Soil Taxonomy (USDA-NRCS, 2010) system of classification has hierarchies of groups of soils (taxa). In this system, the true salt-affected soils belong to the order “Aridisols” and suborder salids. At the third level of classification, there are great groups named Natrargids, which are argids with a high  $\text{ESP}$  and are equivalent to solonetz on the soil map of the world (FAO-UNESCO, 1974). At this third level (great group) of classification, there are also the aquisalids (Plate 2.2a—salids with water table within 1 m from soil surface) and haplosalids (Plate 2.2b—where water table is below 1 m or even deeper) in the suborder of salids, which are equivalent to solonchaks on the soil map of the world.

### 2.2.5 RUSSIAN SYSTEM OF SALINITY CLASSIFICATION

In the Russian classification, the solonchaks may be “external solonchaks” with the soluble salts throughout the whole soil or internal solonchaks with soluble salts in the subsoil or substratum only. The solonchaks are subdivided according to the composition of salts. The following types have been recognized: nitrate, nitrate-chloride, chloride, chloride-sulfate, sulfate-chloride, sulfate-soda, soda, and borate solonchaks. The external solonchaks are of different types (flooded, puffed, sabkha),

**PLATE 2.2** Soil salinity classes (USDA-NRCS): (a) aquisalids—water table at 40 cm and (b) haplosalids—water table at 140 cm.

sometimes the subdivision is made according to the origin of the salt, e.g., closed basin, marine, allochthonous air blown, and anthropic.

## 2.3 SALINITY ASSESSMENT

Accurate measurement is essential to understand soil salinity problem for better management, to improve crop yield and to maintain root zone soil health. If the salinity could be measured, it could be managed. A reliable salinity assessment method is required. The choice of the method, however, depends on purpose, size of the area, depth of soil to be assessed, number and frequency of measurement, accuracy required, and available resources.

There are a number of soil salinity assessment tools, such as salinity monitor maps prepared over a period of time to assess present salinity problem and to predict future salinity risk to the area, salinity indicators on soil surface, vegetative indicators, conventional salinity tests (EC 1:1 or 1:5; ECe) and modern methods (Geophysical—EM38; salinity sensors).

### 2.3.1 REMOTE SENSING AND SOIL SALINITY

Remote sensing acquires information about the Earth's surface without actually being in contact with it. The fundamentals of remote sensing in soil salinity assessment and examples of such studies from the Middle East, Kuwait, Abu Dhabi Emirate, and Australia have been described recently by Shahid et al. (2010). The remote sensing imagery picks surface reflection and provides general salinity information of the area; however, it lacks information about root zone salinity, which requires other conventional (EC meters) and modern methods (EMI and salinity probes) to be used. The combination of salinity maps taken over period of time and digital elevation model (DEM) help predict salinity risk in the area (Furby et al., 1995, 1998).

### 2.3.2 CONVENTIONAL METHODS

Soil salinity measurement is made on georeferenced (using GPS) field sampling, and laboratory analysis of extract from saturated soil paste (Plate 2.3a) by EC meter is accepted as the standard way of soil salinity assessment, expressed as desisiemens per meter ( $\text{dS m}^{-1}$ ) or millisiemens per centimeter ( $\text{mS cm}^{-1}$ ). This is due to the amount of water that a soil holds at saturation, is related to soil texture, surface area, clay content, and cation-exchange capacity. The lower soil:water ratios (1:1, 1:2, 1:5) are also used in many laboratories; however, the results require calibration with ECe to select salt-tolerant crops.

**PLATE 2.3** Salinity assessment methods: (a) saturation extract collection, (b) salinity surveys by EM38, (c) activity meter and probe, (d) placing sensor in the root zone, (e) buried sensor and smart interface and (f) instant viewing of EC on smart datalogger.

### 2.3.3 MODERN METHODS

The salinity assessment and management at farm level help farmers improve crop productivity. The conventional field sampling and laboratory analysis is a tedious, expensive, and time-consuming process. Other quicker and modern methods can be used in the field salinity mapping, such as electromagnetic induction (EMI-EM38) and activity meter with salinity probe. The EM38 (Plate 2.3b) is most commonly used in agricultural surveys and for rapid assessment of the soil's apparent electrical conductivity (ECa) in millisiemens per meter ( $\text{mS m}^{-1}$ ). The EM38 has transmitter and receiving coils. The transmitter coil induces an electrical current into the soil and the receiving coil records the resulting electromagnetic field. The EM38 provides a maximum of 1.5 and 0.75 m depth of exploration in vertical and horizontal dipole modes, respectively. EC mapping is one of the simplest, least expensive salinity measurement tools. Integration of GIS with salinity data results in salinity maps and help farmers interpret yield variations and in understanding subtle salinity differences across agricultural fields, allowing them to develop more precise management zones and, ultimately, potentially higher yields.

Activity meter with salinity probe (Plate 2.3c) is handy equipment and gives instant apparent electrical conductivity (ECa) information in  $\text{mS cm}^{-1}$  and  $\text{g L}^{-1}$ . The German-made PNT3000 COMBI + model is commonly used in agriculture, horticulture, and landscape sites for rapid salinity assessment and monitoring. It provides an extended EC-measuring range from 0 to 20  $\text{mS cm}^{-1}$  and from 20 to 200  $\text{mS cm}^{-1}$ . The unit includes stainless steel measuring electrode 250 mm long for direct soil salinity measurements; EC-plastic probe with platinum-plated ring sensors and high-quality aluminum-carrying case. The operation is convenient and simple; only one button makes the full operation possible. It is essential to validate ECa values with ECe from same fields. In both cases, the ECa must be correlated to ECe for crop salt tolerance.

The most modern salinity logging system (Plate 2.3d through f) is real-time dynamic automated salinity logging system (RTASLS). In this system, ceramic sensors are buried in the root-zone where salinity monitoring is required. Each salinity sensor is fitted with an external smart interface that consists of an integrated microprocessor containing all the required information to

allow autonomous operation of the sensor, including power requirements and logging interval. The smart interface resolution is 16 bit, offering highly precise and accurate recording of the salinity sensor. The smart interface is connected to DataBus, which leads to Smart Datalogger. The Smart Datalogger searches the DataBus and automatically identifies the number of salinity sensors connected and begin logging them at the predetermined intervals. Instantaneous readings from sensors can be viewed on the logger's display directly in the field without the need for a laptop. Data can also be accessed in the field by memory stick or remotely using a mobile phone modem. This data is then available for graphing and interpretation in Excel (Shahid et al., 2009a).

## 2.4 SOIL SALINITY IN IRRIGATED FIELDS AND RELATIVE YIELD PREDICTION

Crops can tolerate salinity up to certain levels without a measurable loss in yield (this is called threshold level). As a general rule, the more the salt tolerant the crop, the higher the threshold level. At salinity levels greater than the threshold, crop yield reduces linearly as salinity increases. Using the salinity values in a salinity/yield model developed by Maas and Hoffman (1977), predictions of expected yield loss can be made. Maas and Hoffman expressed salt tolerance of crops by the following relationship:

$$Y_r = 100 - s(EC_e - t)$$

where

$Y_r$  is the percentage of the yield of crop grown in saline conditions relative to that obtained on nonsaline conditions

$t$  is the threshold salinity level where yield decrease begins

$s$  is the percent yield loss per increase of 1  $EC_e$  ( $dS\ m^{-1}$ ) in excess of  $t$

Salinity mapping at the farm level and Table 2.1 may be used as a guide to predict yield losses.

## 2.5 SALINITY MANAGEMENT AND RECLAMATION

It is essential to keep the plant root zone salinity below crop threshold level to get higher production and to maintain soil health. This requires careful management and reclamation of irrigated agricultural fields. The main objectives of management and reclamation should be to bring more soils under cultivation, to increase the yield per unit area, and to increase the water and fertilizer use efficiency, and to improve livelihood of the farmers. Efficient, effective, and long-term reclamation of saline soils require the lands to be well leveled before leaching is initiated, additional supply of good quality water is required and good subsurface drainage is essential. The physical, hydraulic, chemical, and biological techniques are the methods of soil reclamation.

### 2.5.1 PHYSICAL METHOD

Physical method includes land leveling, salts scraping, deep ploughing and tillage, subsoiling and sanding. In order to remove salts through leaching or flushing, *leveling* (preferable laser leveling) is a prerequisite to allow uniform distribution of water. The objective is to leach the salts or flush from the surface if a near surface restrictive layer is present. The leveling process may compact the soil due to heavy machinery used, subsoiling or chiseling should follow this practice. In certain cases, salt crusts formed at surface can be removed by mechanical means. In small agricultural farms, salt *scraping* is the simplest and most economic way of reclaiming saline soils. Scraping can minimize

Notes: s, % yield loss per 1 ECe (dS m<sup>-1</sup>) increase above t (ECe) value; t, salinity threshold ECe (dS m<sup>-1</sup>), where yield is optimum.

the salts temporarily; however, they can reappear with a continuous feed of ground water to the surface. Low salinity in the rootzone can be achieved through *tillage* practices by manipulating the soil surface condition, i.e., bed shape and irrigation management (Plate 2.4a). It is very well recognized that salts tend to accumulate on the ridges top away from the wet ridge shoulder (Plate 2.4b) when furrow irrigation is adopted. Placing the seeds on off-center slope of the single row will put the seed (Plate 2.4a) in minimum salinity and optimum moisture condition. Under high salinity, the alternate row should be left unirrigated; this will ensure maximum accumulation of salts in the unirrigated area and leave the irrigated furrows free of salts and fit for planting seeds (Plate 2.4b and c). *Subsoiling* is particularly important for disrupting the dense layers (Plate 2.4d) at depth to enhance permeability (Shahid et al., 2009b). In the absence of subsoiling, flushing should be preferred over leaching; the latter compounds the salinity problem in the root zone due to the dense layer. Subsoiling is important while reclaiming sodic soils after the addition of a suitable amendment such as gypsum and watering the field.

If the soil surface to be reclaimed is very heavy textured, mixing of sand, “sanding,” to the surface can change the texture permanently, and the soils become more permeable and easy to reclaim. This practice also provides a favorable environment for plant growth compared to the original soil without sanding.

**PLATE 2.4** Seed bed, salinity development, and plant growth: (a) Seed placement on furrow shoulder, (b) salt accumulation on ridge tops, (c) barley plants growing on ridge shoulder, and (d) dense layer need subsoiling.

### 2.5.2 HYDROLOGICAL METHOD

Hydrological method is concerned with water use and drainage. In irrigated agriculture, the objective is to free the root zone from salts through leaching to lower depths and the subsequent drainage and surface flushing of dissolved salts. The rootzone salinity may increase if the net downward movement of salts is less than the salt input from irrigation, and salt water flux to surface. Therefore, salt balance must be kept under control, and this is a function of irrigation water salinity and to the success of drainage system.

Traditionally, saline soils have been reclaimed by flooding or by ponding water. In general, the depth of soil leached is roughly equal to the depth of water infiltrated during leaching. In order to leach the salts, the leaching requirement (LR) is very important. The LR is the calculated fraction (depth) or quantity of water that must pass through the rootzone to maintain the EC of the drainage water at or below some specified level. The recent trend is to minimize this LR in order to prevent raising the groundwater and minimize the load to drainage system (Mashali, 1995). Methods of LR calculation and to predict the losses in yield due to salinity are described by Rhoades (1992).

Timely leaching is important to assure root zone salinity is not exceeded above crop salinity tolerance limit for extended periods of time or critical stage of plant growth. In normal conditions, leaching can be accomplished at each irrigation; however, in soils with low infiltration rate and for crops sensitive to excess moisture in the rootzone, leaching at each irrigation may not be appropriate. Leaching can be done when soil moisture is low and water table is deep; it should precede the critical growing stage; at low evapotranspiration demand; at night, during high humidity, in cooler weather and; at the end of cropping season, as appropriate to area.

The drainage lowers water table, provides adequate leaching, minimizes upward water flux, and thus controls salinity buildup. Provided the subsurface is permeable and relief is adequate, natural

drainage may work; however, experience shows that such ideal conditions do not prevail in saline areas, and therefore, a drainage system is always required. Based on site condition, nature of the problem, and available resources, a suitable drainage system (surface or subsurface) can be selected. Surface drainage allows runoff excess water before entering to soil and subsurface drainage is used to control water table at safer depth, consisting of open ditches or tile drains or perforated plastic pipes, mole drainage, and vertical drainage (pumping water) when the deep horizons have an adequate hydraulic conductivity.

2.5.2.1 Modern Irrigation Methods

In arid and semiarid zones, the major constraints are limited quantities of good quality water and to increase its efficiency; and exploitation of unsuitable brackish/saline water for irrigation. Therefore, a suitable irrigation method is to be selected without invoking soil salinity hazards. Each irrigation system develops salinity at a specific soil zone that is to be carefully monitored.

*Surface* irrigation includes flood, basin, border, and furrow methods. At the end of each irrigation cycle, soil dries out concentrating the salts, which adversely affects the crop yield. Frequent irrigation may lower the salinity, but increase the wastage of water; the alternatives to improve the efficiency of water are the drip, subsurface, or sprinkler irrigation. This shift from conventional surface irrigation to modern irrigation is costly and requires assurance on better crop adaptability.

A good *sprinkler* irrigation must meet the requirements of the crop for water (ET). It often allows efficient and economic use of water and reduces deep percolation losses. If water application through sprinkler is in close agreement with crop needs (ET and leaching), drainage and high water table problem can be greatly reduced, which in turn should improve salinity control. The use of high salinity water may lead to leaf burn and, therefore, the quality of water must match with the leaf burn tolerance of plants. Under sprinkler irrigation, the net salinity built up is at subsurface.

The *drip* (trickle) irrigation supplies the required quantity of water to the crop almost on a daily basis. The poor quality water used in drip irrigation may yield better due to continuous high moisture contents and daily replenishment of water loss by ET. Drip has priority over sprinkler as the latter may cause leaf burn, defoliation of sensitive species, which is not the case with drip irrigation. Maximum salt accumulation is outside the edges of the area wetted by emitters (Plate 2.5).

PLATE 2.5 Drip irrigation and salt accumulation (salinity map).

The daily irrigation continuously moves the moisture down to keep the salts under control. Plants may get shock due to high salinity when rainfall, as the rain water pushes the salts from edges to central rootzone; it is advisable to not shut the drip irrigation during rainfall to push the salts continuously toward the edges of the area wetted by emitters.

*Subsurface drip irrigation* (SDI) compared with other irrigation systems SDI reduce water losses to evaporation, deep percolation, and completely eliminate surface runoff (Phene, 1990), increase crop marketable yield and quality (Ayers et al., 1999), and can result in high nutrient use efficiency (Thompson et al., 2002). Saline irrigation water can be used with SDI, while maintaining yields and improving water use efficiency compared to surface irrigation (Tingwu et al., 2003; Cahn and Ajwa, 2005) because SDI can result in suitable root-zone salinity. The limitation of SDI is that salts continuously build up at surface through capillary action above the buried drip lines during growing season (Oron et al., 1999) and therefore the concept of LR does not work under SDI; however, salts above buried drip (surface salinity) can be managed by supplementing with sprinkler irrigation (Thompson, 2010). This approach may be costly, but a compromise.

### 2.5.3 CHEMICAL METHOD

Chemical methods are used to reclaim sodic soils. To have successful crops on sodic soils, ESP of the soil must be below threshold ( $<15$ ). The main aim is to increase the concentration of calcium in the soil. The long-term objective is to replace ES with calcium, and use organic matter to bind the soil and improve its structure. Gypsum ( $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ) is commonly used amendment (to supply Ca) to rectify sodicity problem in irrigated fields. Calcium causes particles to form clusters (floculates), forming a very clear puddle of water. Gypsum addition changes the soil chemistry in two ways: (1) by increasing salt solution clay do not swell and disperse. This is a short-term effect, which occurs as the gypsum dissolves; (2) the calcium from gypsum replace the ES attached to the clays (exchange complex). The process changes a sodic clay to a calcium clay, making it less prone to swelling and clay dispersion. The displaced sodium cations are leached below the plant root zone. Mined gypsum (10 mesh) is commonly used.

The addition of HCl and  $\text{H}_2\text{SO}_4$  is only recommended where soils are sodic and calcareous. The acid induces Ca from  $\text{CaCO}_3$  and Ca released work in similar manner as from gypsum. Acids are highly corrosive and dangerous to handle; special equipments are available to apply acid in the field and usually it is applied with irrigation water.

Addition of elemental sulfur may also be useful in reclaiming sodic soils, with the condition that it is properly oxidized. The sulfur (S) may be oxidized through biological oxidation by *Thiobacillus thiooxidans*, in sodic soils it is very slow process. The final product is  $\text{H}_2\text{SO}_4$ .

### 2.5.4 BIOLOGICAL METHOD

#### 2.5.4.1 Serial Biological Concentration of Salts

The concept of serial biological concentration of salts (SBCS) (Heuperman, 1995) may provide an alternative salt management option, especially where groundwater pumping and safe disposal is an issue. The objective of SBCS is therefore to lower water table and reduce water volume. The SBCS system involves reuse of drainage water on progressively increasing salt-tolerant crops (salt-sensitive crops, salt-tolerant crops, halophytes, trees, etc.). In SBCS cropping system, each crop is underlain by tile drain for the collection of water to be used to irrigate the next stage. Along the crop sequence, the volume of drainage water collected is reduced due to plant water use, and the salinity of the drainage water increases since there is little or no salt uptake by plants. The highly saline water can be either transferred to treatment plants where through reverse osmosis or other techniques, it can be treated and salts can be removed, or the final effluent is contained in relatively small evaporation ponds making it feasible to consider the use of floor lining to eliminate leakage. These ponds

could be used for fish farming. The highly saline water may be collected in a series of ponds where through evaporation salts may be harvested, and may have commercial value such NaCl (halite) for caustic soda factories and other uses.

#### 2.5.4.2 Biosaline Agriculture (Practicing Salt-Tolerant Crops)

Biosaline agriculture means economic utilization of salt-affected soils, saline/brackish waters for agricultural purposes. It involves cultivation of salt-tolerant species of agricultural significance and adoption of special agronomic practices to improve their productivity under such conditions. Some scientists use saline agriculture concept, but “biosaline” is much broader in scope and includes manipulation of desert and sea resources for food and fuel (energy) production. Tables for salt tolerance of different crops are reported elsewhere (Maas, 1990).

For practical biosaline agriculture, the very first step is to identify the nature of the problem and then to visualize appropriate measures for maximum economic returns under the specific situation. Biosaline agriculture has many dimensions such as selection/breeding of salt-tolerant genotypes and plant species; domestication of salt-tolerant wild plant species for economic exploitation of salt-affected lands; introduction into the cultivated crops/other plant species genes of salt tolerance from their wild relatives through genetic engineering; agronomic practices including methods of land preparation, planting, irrigation and fertilizers application; and physiological studies with the following objectives. Other aspects in biosaline agriculture are; (1) to determine critical plant factors controlling yield under saline conditions, (2) to study physiological differences between salt-tolerant and salt-sensitive genotypes with a view to develop selection criteria for salt tolerance, (3) to improve yield through special treatments at critical stages during plant growth, and (4) the use of salty water for agricultural purposes. The Dubai based International Center for Biosaline Agriculture is specialized in such studies and have developed various production systems and introduced in many countries (Pakistan, UAE, Oman, Tunisia, Syria, Jordan, Palestine, Uzbekistan, etc.) for saline soils.

#### 2.5.5 ALTERNATIVES FOR USING MARGINAL SALINE LANDS

There are persuasive reasons to extend the range of agricultural production into more saline environment. Some of these areas are uneconomical to reclaim by conventional soil reclamation procedures, e.g., leaching of salts and their drainage and use of chemical amendments. On such areas, the management and improvement of wild stands of *Atriplex* (salt-bush) for grazing have been pursued for many years in Australia. Now, there is increasing interest in cultivating, breeding, and managing selected *Atriplex* species for intensive forage production with highly saline water (Plate 2.6a).

Halophytes are one choice for such soils; they can grow under very saline conditions, for example, *Juncus vigidus* and *J. acutus* can grow in saline marshes or under irrigation with brackish water

(a)

(b)

**PLATE 2.6** Alternative use of saline lands: (a) *Atriplex* growing in inland salt flat (sabkha) and (b) coastal mangroves in Abu Dhabi Emirate.

or even seawater. The culms provide fibers for high-quality paper production and the seeds have the medicinal value. The *Leptochloa fusca* (kallargrass) as forage, green manuring, compost, crop, pulp for paper production is found to be salt-tolerant in almost any salt-affected soils in most areas even irrigated with highly sodic water. Mangroves grown in coastal areas (Plate 2.6b) are other options; they provide fuel and fodder and deserve more attention for planting along shorelines. The sites may also be used for recreation purposes.

## 2.6 ECONOMIC, ENVIRONMENTAL, AND SOCIAL LOSSES DUE TO SOIL SALINITY

Economic losses are faced through loss of agricultural production and costs are incurred for land rehabilitation for public utilities.

Environmental losses are introduced through land degradation by physical, chemical, and biological changes in the soils and waterways, loss of vegetation and change to the landscape.

Social losses include an increased production costs on farms and reduced value of land as a result of soil salinization. The person from the salinized area move away and the social set up is disturbed.

## 2.7 RESEARCH–EXTENSION–FARMER LINK

There should be strong link of research–extension–farmers to benefit the end chain member (farmers, the stakeholders). Therefore, education to farming community is vital in increasing awareness and understanding of salinity. Advisory program should be developed to help farmer's plan and use salinity control practices on their farms. Salinity mapping on whole farm scale is the best practice for crop selection. Farmers should realize the significance of salinity mapping for the sustainable use of their farms. Salinity exhibitions for community education should be arranged in government institutes; demonstration days at the farmer's field are also useful. Preparation of introductory brochures for salinity control and management at the farm level and their distribution to the farming community can enhance their understanding to tackle salinity in a sustainable way. The awareness of the problem to teachers gives students hands-on experience and helps them discuss options with their students. After all, today's students will be tomorrow's soil resource users and managers.

## 2.8 SUMMARY

Salt-affected soils are a major global issue owing to their adverse impact on agricultural productivity and sustainability. Soil salinity/sodicity undermines the resource base by decreasing soil quality. This could be natural or a symptom of misuse and mismanagement that jeopardizes the integrity of soil's self-regulatory capacity. Recent estimates show that salt-affected soils occur throughout the world. The countries affected by salinization are predominantly located in arid and semiarid regions where continued irrigation with low-quality groundwater has contributed the expansion of salt-affected soils. In order to exploit these soils to their full potential, there is a need for a sound basis to optimize their use, determine their potential, productivity, and suitability for growing different crops, characterize these soils, and identify appropriate integrated reclamation and management practices. Management and reclamation can only be achieved if causes rather than the symptoms are identified and controlled. In this chapter, technologies for the characterization, reclamation, and management of salt-affected soils are described. In addition, different classification systems of salt-affected soils adopted in the world as well as soil reclamation technologies including hydraulic, physical, chemical, and biological approaches are described. Moreover, some possible alternatives to utilize the salt-affected soils are also discussed. Finally, link between research–extension–farmers has been proposed. The chapter demonstrates an easy format and language that is designed to be user-friendly.

## 3.1 INTRODUCTION

### 3.1.1 FOOD PRODUCTION AND IRRIGATED LAND

The dramatic increase in total global food production over the last 50 years has avoided the predictions of large-scale food famine. In addition to the increase in cultivated land, there has also been an increase in crop production on a per-acre basis. This increase is generally attributed to the development of improved crop varieties and management practices (green revolution); however, an important part of this increase is related to an increase in the amount of irrigated acreage. Irrigated lands have much higher productivity and economic return per acre as compared to nonirrigated lands. For example, it is estimated that globally, irrigated lands represent 15% of the cultivated land, yet they produce over 30%–40% of the world's food (Ghassemi et al., 1995; Postel, 1999). In arid regions, the impact of irrigation is much greater than the rest of the world in general. Arid regions have low production in the absence of irrigation due to insufficient water to meet crop needs. Also, most arid lands are located in high-temperature environments, and, therefore, with adequate water they can be almost continually cropped, with multiple harvests. The 35% increase in irrigated land from 1970 to

the late 1980s thus provided a significant part of the increase in world food production and was a major factor in avoiding large-scale famine.

Since the 1980s, there has been a decline in the rate of growth in the world's irrigated land. By the start of the twenty-first century, total irrigated acreage reached a constant value. The stabilization in total irrigated acreage is due primarily not to lack of additional suitable arable land or financial resources, but rather to the lack of new developable water supplies in most of the arid and semiarid regions that can most benefit from irrigation.

The current levels of irrigation in arid regions are clearly not sustainable with existing water supplies. Supplemental irrigation in more humid regions has increased, masking the actual decline in irrigated acreage in arid regions. Globally, irrigated agriculture uses approximately 65% of the total fresh water, with the industrial and municipal sector making up the balance. California in the United States has experienced significant declines in irrigated acreage. For example, during the 2009 irrigation season, over 180,000 ha were taken out of irrigation in the Central Valley, with the likelihood that there will not be sufficient water in the future to bring this land back into production. "Land banking" is occurring in other irrigation districts, such as Palo Verde and Imperial, where long-term contracts have been signed in transferring former irrigation water to municipal water entities. Additional declines in irrigated acreage are occurring due to the partial restoration of natural water flows for environmental considerations. Future declines are anticipated due to declining ground water supplies as well as increasing urban and environmental water demands. Currently, the percentage of fresh water used by agriculture in California has declined from 75%, as recently as 20 years ago, to below 50%, with a corresponding increase by percentage used by the municipal sector and a decrease in overall use.

Unfortunately, most arid regions do not have new developable surface waters, and the current large fresh water extractions of ground water required for irrigated agriculture cannot be sustained let alone increased. This overutilization of fresh water, extracting what is often called fossil water, is particularly severe in drier regions of the world, where population density, poverty, and food demands are greatest. Overdrafting of ground water has resulted in declining water tables, loss of shallow fresh water for municipal use, and sea water intrusion in coastal regions. In the early 1990s, approximately one-fifth of the irrigated lands in the United States were extracting groundwater in excess of their natural recharging capacity (Postel, 1997). The data are not completely known, but the situation appears more severe in many less developed nations in arid and semiarid regions.

An increasing population results in increasing total demand for fresh water for municipal and industrial use as well as for increased food production. Increased fresh water needs are also related to increased per capita water usage associated with improved economic conditions in a region. Increases in living standards are not only related to increased domestic per capita water consumption, but they also result in increased water consumption related to food production on a per capita basis. This increased demand with improved living standards is related to the increased water requirement for meat production versus grain production (expressed as gallons or liters of water per kcal). It will be a major challenge just to maintain the existing level of irrigation and associated food production in the arid and semiarid regions of the world. An increase in living standards will require yet more water.

## 3.2 SALINITY

### 3.2.1 EXTENT OF SALINITY PROBLEM

It is estimated that there are 76 million hectares (Mha) of human-induced salt affected land, representing 5% of the world's cultivated land (Ghassemi et al., 1995). Salt affected lands are those where crop yields are reduced or where less desirable crops must be grown because of the salinity. This human induced salinization is termed secondary salinization, in contrast to regions that were saline

in their native condition. This value underestimated the extent of salinity because it does not include large areas of land that could be potentially cultivated, if not for the native salinity.

Salinity problems are most prevalent in irrigated lands relative to the total cultivated acreages. This is not surprising as irrigated lands are concentrated in more arid regions, where salinity is more likely to be a problem. Also, irrigation results in the application of additional water to the landscape, thus imposing additional drainage needs to the natural hydrologic system. Of the world's 227 Mha of irrigated lands, it is estimated that 45.4 Mha, or 20%, are adversely impacted by secondary salinization (Ghassemi et al., 1995).

Salinity is a major threat to current irrigation projects and to the remaining near-surface fresh water supplies in arid regions. The extent of the salinity problem has not stabilized; instead, it is estimated that as much as 2 Mha of irrigated land, representing approximately 1% of the total, is lost from production due to salinity each year (Umali, 1993, in Postel 1997). Most of the world's salt affected, cultivated lands are in Asia and Africa, where population densities and economic conditions make the problem proportionately more severe. For example, it is estimated that Egypt, Iran, and Pakistan had 33%, 30%, and 26%, respectively, of their irrigated land impacted by secondary salinization (Ghassemi et al., 1995). Developed countries are not immune to these salinity problems. For example, it is also estimated that over 20% of irrigated land in the United States is salt affected (Postel, 1999), a value comparable to the global average.

### 3.2.2 MANAGEMENT IMPACTS

In contrast to salinization of water supplies, soil salinization is generally more readily controlled. Most soil salinization has historically occurred as a result of over-irrigation. For earlier civilizations, this can be partially attributed to lack of knowledge concerning water use or requirements relative to quantities of water applied.

In the past two centuries, over-irrigation and salinization can mostly be attributed to two factors: the design and operation of irrigation projects, and overemphasis on the need for leaching. Irrigation projects have been designed without sufficient coordination between plant scientists, irrigation scientists, and civil and hydraulic engineers. Irrigation specialists, focused on the development of new irrigation projects, have emphasized the need to leach salts out of the root zone to enable maximum yields. The concept was that salts had to be "pushed" down into the profile to avoid surface salinization and crop failure; the more leaching the better.

With initially abundant water, older irrigation systems were typically developed with earthen canals and laterals, and irrigation was by furrow or wild flooding, resulting in nonuniform water application. The limitations of these irrigation systems, combined with the overemphasis on leaching, have resulted in low irrigation efficiency. In many, if not most, instances the large delivery system water losses and excessive water applications result in large drainage volumes to the subsurface, in excess of natural drainage capabilities. Excessive drainage volumes, in turn, usually results in subsequent water logging, evaporation of water from the surface, and deposition of salts at or near the soil surface in low lying parts of the irrigation district. Expensive drainage systems are subsequently often constructed, controlling the root-zone salinity but discharging large volumes of saline water to the drainage system, typically causing adverse salt impacts to downstream users.

Increased salinization in arid and semiarid regions is also often caused by leaching of existing salts from the soil during irrigation in regions containing strata with high salt, as well as by application of waters of low quality without proper management. In the instance of soils high in native salts, regional salinization of ground and surface waters is aggravated by excessive water applications. The impacts of leaching salts present before irrigation may be observed for over a period of 120 years after initiation of the irrigation project (Grand Valley, Colorado), depending on the hydrology of the system, type of salts present, and depth and design of the drainage system, if present.

### 3.2.3 SALINIZATION OF WATER RESOURCES

In addition to the unsustainable extraction of fresh water, there is a related decline in water quality of existing supplies; thus, these factors are not unrelated. There are two general factors contributing to the decline in water quality. Extraction of fresh water from a system reduces the extent of dilution of other natural or man-induced salt loads. Second, as irrigation brings more salts into a valley, it adds a new source of drainage of additional saline water into the receiving body of water. These concentrated drainage waters contain both the initial salts present in the irrigation water as well as salts already in the soil that are displaced by the water leaving the root zone. Thus, in arid regions, irrigation or even changes in cropping patterns that impact recharge often mobilizes salts that have accumulated over geologic time either in the unsaturated zone, salinizing groundwater (Australia), or displacing saline groundwater into rivers (Grand Valley, Colorado and the Colorado River). Again, due to the long flow paths, this additional salt load can continue for an additional 150 year, consistent with hydrologic model predictions.

Salinity increases in the drainage water relative to irrigation water are inevitable. Plants extract water, preferentially, thus concentrating these salts in the remaining soil water. Typically, plants contain only 5%–10% of the salt associated with the volume of water that they extract. Hence, more efficient irrigation (generally resulting in less water applied more uniformly), while desirable, results in smaller volumes of drainage water, but of greater salinity. The salinity increase is approximately inversely proportional to the change in volume (inverse to volume of irrigation water/volume of drainage water). Salinization of water resources, especially ground water, is a slower process than soil salinization, but is much more difficult to remediate.

## 3.3 WATER QUALITY CONSIDERATIONS

### 3.3.1 MEASURING AND REPORTING SOIL SALINITY

It is logical that salinity be reported in terms of concentrations of salts, either as total dissolved solids (TDS) in units of mg/L or g/L or as molar quantities, mol/L. From the perspective of plant response, it is generally considered that the adverse effect is related to the osmotic pressure (OP) of the soil solution. However, it is most convenient to measure the specific electrical conductance (EC), typically reported in dS/m at 25°C. As can be expected, the EC is highly correlated with the concentration of total salts, expressed in mol/L or mmol/L of charge. The widely used approximation

$$\text{TSS (mmol}_c\text{/L)} = 10 \text{ EC (dS/m)} \quad (3.1)$$

where TSS, the total soluble salts (U.S. Salinity Laboratory Staff, 1954), is useful for low to moderate salinity (<5–7 dS/m) as the relationship depends on concentration. Alternatively, the relationship

$$\log \text{ TSS} = 0.990 + 1.055 \log \text{ EC} \quad (3.2)$$

(Marion and Babcock, 1976) can be used, but it is still only an approximate, as the relationship between EC and salt concentration also depends on the ion composition of the salts. A more detailed and accurate estimation than provided by these equations, such as that developed by McNeal et al. (1970), requires knowledge of the solution ion composition for prediction of EC.

As the salinity of water increases upon concentration by the processes of evaporation and transpiration, the relative proportions of sodium and chloride increase due to solubility considerations. The most important minerals affecting solution composition are calcite and gypsum, controlling calcium, bicarbonate, and sulfate ions concentrations. Additionally, various salts, including magnesium silicates (sepiolite) and sodium sulfates, may precipitate at very elevated salinity, depending on the composition of the initial solution.

Calculation of mineral solubility requires calculation of ion activity coefficients, ion pairs, and complexes in order to obtain ion activities. The calculation methods are not presented here, as accurate calculation requires a computer model, of which many are readily available. The major ions in saline waters in general order of occurrence are  $\text{Cl}^-$ ,  $\text{Na}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{SO}_4^{2-}$ ,  $\text{HCO}_3^-$ ,  $\text{NO}_3^-$ , and  $\text{K}^+$ .

Often soil extracts are prepared to measure soil salinity and solution ion composition. Addition of water inevitably changes the solution composition by mineral dissolution and cation exchange. Thus, the desired extract from the chemical consideration is the one with the lowest addition of water that can result in water extraction. The saturation extract (U.S. Salinity Laboratory Staff, 1954) is generally used as it results in relatively low addition of water and allows for estimation of soil solution EC at field capacity, since there is an approximate ratio of soil solution at field capacity to extraction paste water content. Other extractions in common use include the 1:1 and 1:2 soil: water ratio extracts. Although these are much easier to prepare, they result in greater dilution of the soil solution. In addition, these extracts have a more variable ratio of field capacity water content/extract water content, as compared to the ratios for saturation extracts.

Prediction of the EC, OP, and solution composition with changing water content upon dilution can be made with the Extract Chem model (Suarez and Taber, 2007), which considers mineral equilibrium, cation exchange, and B desorption. The model can be utilized to convert/extract data from one water content to another (such as converting 1:1 extract concentration data into saturation extract concentration data). This conversion is important in the interpretation of salt-tolerance data, as different reference water contents are utilized in these studies.

### 3.3.2 SODIUM AND pH EFFECTS ON SOIL PHYSICAL PROPERTIES

Waters of increased salinity inevitably contain greater proportions of Na and to a lesser extent Mg relative to Ca, due to solubility considerations. The adverse effects of sodium on soil saturated hydraulic conductivity, (McNeal and Coleman, 1966; Shainberg et al., 1981; Suarez et al., 1984), clay swelling, (McNeal et al., 1966), and clay dispersion and flocculation (Frenkel et al., 1978; Goldberg et al., 1988; Suarez et al., 1984) are well documented. The adverse effect of sodium on soil physical properties is a major concern when using waters of lower quality for irrigation.

The SAR (sodium adsorption ratio) is defined as

$$\text{SAR} = \frac{\text{Na}^+}{(\text{Ca}^{2+} + \text{Mg}^{2+})^{0.5}} \quad (3.3)$$

where concentrations are in mmol/L. Inspection of Equation 3.3 indicates that SAR increases with increasing salinity due to the square root term for divalent ions in the expression, as well as the earlier mentioned increase in the proportion of  $\text{Na}^+$  ions with increasing salinity. The SAR is related to the exchangeable sodium percentage (ESP) in the soil by the following expression:

$$\frac{[\text{ESP}]}{[100 + \text{ESP}]} = k'_g \text{ SAR} = \text{ESR} \quad (3.4)$$

(U.S. Salinity Laboratory Staff, 1954), where  $k'_g$  is a cation selectivity coefficient, typically assigned a value of  $0.015 \text{ (mmol/L)}^{-0.5}$ , thus irrigation with more saline waters almost always results in increased exchangeable sodium.

In addition to direct determination of the SAR of irrigation water, it is important to consider the resultant SAR in the soil solution. The SAR depends on the calcium concentration in solution, which in turn depends on the solubility of calcium carbonate. Ground waters are often equilibrated

at carbon dioxide levels 10–50 times greater than atmospheric. Upon degassing of previously calcite saturated water, calcite precipitates and the calcium concentration in solution decreases. The adjusted SAR concept was developed to consider the change in calcium concentration upon equilibration of irrigation water to earth surface conditions.

The simplest and relatively accurate way to calculate an adjusted SAR is to utilize the following equation (Suarez, 1981):

$$\text{SAR}_{\text{adj}} = \frac{\text{Na}_{\text{iw}}}{\sqrt{(\text{Mg}_{\text{iw}} + \text{Ca}_{\text{eq}})}} \quad (3.5)$$

where  $\text{Ca}_{\text{eq}}$  is the Ca concentration (in mmol/L) in equilibrium with calcium carbonate in the soil. For predictive purposes, we utilize a value that is threefold greater than calcite solubility, since this value is the mean value determined for waters below the root zone (Suarez, 1977). The values of adjusted SAR can be obtained directly from computer models such as Extract Chem. (Suarez and Taber, 2007) or  $\text{Ca}_{\text{eq}}$  can be obtained from Tables in Suarez (1981) or by the following equation (Lesch and Suarez, 2009):

$$\text{SAR}_{\text{adj}} = \frac{\text{Na}_{\text{iw}}}{\sqrt{\text{Mg}_{\text{iw}} + 0.215X(P_{\text{CO}_2})^{1/3}}} \quad (3.6)$$

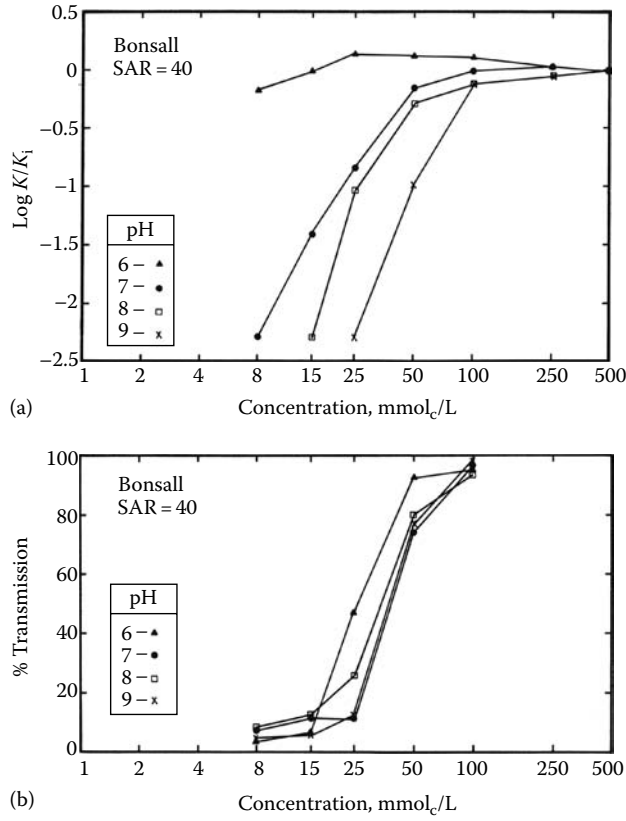

where  $X(P_{\text{CO}_2})^{1/3} = \text{Ca}_{\text{eq}}$ . The  $X$  value considers the equilibrium constants and  $\text{Ca}/\text{HCO}_3$  ratio. The  $P_{\text{CO}_2}$  of surface waters can be represented by the value of  $10^{-3.14}$ , or twice atmospheric.

It is generally considered that the elevated SAR associated with saline waters is not of concern, since the infiltration of these waters is not adversely impacted according to guidelines for sodium hazard (Ayers and Westcot, 1985). However, their analysis does not consider the impact of rain, which results in a rapid decrease in soil salinity at the surface, with a much slower reduction in the exchangeable Na. Computer simulations of changes in exchangeable sodium upon rain on a sodic soil (Suarez et al., 2006) confirm the observed decrease in infiltration that is observed in studies with cyclic rain and irrigation events over an irrigation season (Suarez et al., 2006, 2008). Thus, even in regions where rainfall is an insignificant contribution to the water budget, the dispersive effect of sodium is a significant concern and generally indicates the need to apply a surface soil amendment (such as gypsum) when using waters with  $\text{SAR} > 3$  for irrigation.

The pH of the irrigation water is an important factor related to soil physical properties and infiltration, independent of SAR. Almost all soil hydraulic conductivity studies examining water composition effects utilized chloride as the anion, thus  $\text{pH} < 7$ . Increasing pH also enhances clay dispersion and reduces saturated hydraulic conductivity (Suarez et al., 1984). As shown in Figure 3.1a (Suarez et al., 1984), the relative hydraulic conductivity of an arid land soil at constant  $\text{SAR} = 40$  decreased with decreasing solution concentration. At pH 6, the hydraulic conductivity decreased slightly, while with a further increase in pH the hydraulic conductivity progressively decreased. Related results were obtained from measurements of optical transmission of solutions of soil clay and water that were measured after some fixed times. These measurements represent the process of clay flocculation, as shown in Figure 3.1b (Suarez et al., 1984). Upon comparison of Figure 3.1a with Figure 3.1b, we conclude that although the flocculation tests are simple and quick to perform and provide a useful indication of potential soil dispersion, they do not duplicate the response of the more important hydraulic properties of the soil.

### 3.3.3 WATER QUALITY CRITERIA RELATED TO SOIL PHYSICAL PROPERTIES

There are many factors that relate to soil stability. From the point of view of irrigation of arid land soils, the focus has been on the electrical conductivity (or salt concentration) and the SAR of the irrigation water. The EC-SAR guidelines, presented in a FAO publication by Ayers and

**FIGURE 3.1** (a) Relative hydraulic conductivity and (b) optical transmission of Bonsall soil as related to electrolyte concentration and pH. The saturated hydraulic conductivity was recorded from step-wise reductions in solution concentration at constant SAR. (After Suarez, D.L. et al., *Soil Sci. Soc. Am. J.*, 48, 50, 1984.)

Westcot (1985) have been widely used, generally without consideration of the uncertainty associated with the guideline. The representation presents two stability lines, one for severe effects and the other for slight to moderate reduction in infiltration. Waters with SAR less than the point on the line but at the same concentration or with EC greater than the point on the line, but with the same SAR, were deemed safe to use. However, there is considerable uncertainty as the water hazard depends on many other factors, including pH, organic matter content, Fe and Al oxide content, clay mineralogy, tillage, irrigation system (sprinkle, flood, drip) previous tillage, initial infiltration rate, etc. As shown by Pratt and Suarez (1990), there is a large variability associated with the represented stability line, although there is a good relationship between stability and SAR-EC for any specific experiment.

One of the important factors is the interaction of rain with the irrigation water. It is not sufficient to average the water compositions, as the input of rain causes a rapid decrease in the surface soil EC and a correspondingly smaller decrease in the SAR, as the soil exchangeable cations buffer changes in solution SAR. This effect is greater for soils with high cation exchange capacity.

Almost all studies of chemical effects on soil properties are based on short-term experiments with disturbed soil under continuous saturation. Suarez et al. (2006) demonstrated that the long-term effects on infiltration are more severe than current guidelines indicate. The revised water quality graph shown in Figure 3.2 (Suarez, 2010) represents pH dependent effects on infiltration as well as the EC and SAR interactions. It is emphasized that these are only guidelines and different responses may be expected for soils of varying stability.

**FIGURE 3.2** Sodicity hazard of irrigation water on water infiltration as related to EC, SAR, and pH. (After Suarez, D.L. Irrigation water quality assessments, in *Agricultural Salinity Assessment and Management*, ed. W. Wallender, Chap. 11, *Am. Soc. Civil. Eng.*, New York, 2010, in press.)

### 3.4 MANAGEMENT OPTIONS

#### 3.4.1 IMPROVED DELIVERY SYSTEMS

Ensuring that soils are not over-irrigated and maximizing the food production per unit of water applied requires changes in irrigation systems and management. Most improvements to date have been done on the engineering side, with relatively less change on the agronomic side. For example, conversion of surface flooding or furrow to sprinkler allows for more uniform application of water, reduced need for irrigation water, and reduced drainage volumes. Application of drip irrigation systems allows for uniform delivery of water to plants or trees in the field, while avoiding wetting of the entire soil surface. These system changes and associated changes in management practices require capital investments and education programs for irrigators. Nonetheless, these systems are less costly than development of new water supplies, especially the use of desalinated water.

In the instance of Grand Valley, Colorado, improved water delivery and management was essential for salinity control in the valley as well as for reduction in salinity in the lower regions of the Colorado River that receive the return flows. Improvements in irrigation system infrastructure and management in Grand Valley Colorado, including concrete lining of canals and laterals, installation of closed pipe delivery systems, and irrigation scheduling are calculated to have reduced the salt load to the Colorado River by approximately 500,000 ton per year.

#### 3.4.2 WATER REUSE

As discussed above, secondary salinization due to over-irrigation and insufficient drainage is the major cause of soil salinization in irrigated lands. Reuse of drainage water, where feasible, provides the opportunity for alternative water resources in water-short regions, as well as water-table control. A significant concern regarding the reuse of drainage water is its impact on the soil, and the potential salinization from applying more saline irrigation water on an already saline soil. However, Corwin et al. (1998) observed a decrease in soil salinity, and partial reclamation of sodic

soil conditions where drainage water more saline than presently formerly used irrigation water was applied. The benefits may be from several factors including a drop in the perched water table below the field, allowing for better drainage, as well as improved infiltration related to application of more saline water and application of greater volumes of water.

Maintaining irrigation in arid regions will require maximum utilization of sustainable water supplies. Water reuse is a necessary aspect of this system, but it should be looked at as a complimentary practice rather than as an alternative strategy for water management or as an alternative to reduction in drainage volumes. The ideal water use is still to extract the maximum benefit from the initial fresh water application, minimizing the volume of drainage water generated. This minimizes the need for drainage and avoids the mixing and degradation either of fresh water, if the drainage returns to a water supply such as a river, or else degradation of the drainage water by mixing with a saline ground water. This concept has been often dismissed as impractical. It has been argued that as crops vary in salt tolerance, application of water quantities at or near ET is feasible only for salt-tolerant crops if the irrigation water has any appreciable salinity. This argument is examined in the subsequent section.

### 3.4.3 REDUCTION IN QUANTITIES OF LEACHING WATER

The possibilities of using saline waters at low leaching fractions have been significantly overlooked due to use of current guidelines, such as Ayers and Westcot (1985). The major justification for application of water in excess of crop requirements has been the need to leach salts out of the root zone and thus control root-zone salinity. The leaching requirement concept provides for calculation of a crop-specific quantity of leaching water in addition to that consumed by the crop that must be applied to avoid yield loss to salinity.

The use of the static leaching requirement calculation is being questioned on several grounds. Most importantly, as demonstrated in an example below, the concept does not consider the decrease in water uptake and thus increase in leaching that occurs when plant yield decreases. The leaching fraction is thus not a fixed input variable but rather a result of water applications, potential ET, and plant response.

Secondly, the method used to calculate plant yield as related to salinity of irrigation water usually involves a simplified calculation of root-zone salinity, and the root-zone average value is used (Ayers and Westcot, 1985) rather than a water-uptake calculated value. The salinity in the deeper portions of the profile is greater than that near the surface, where the roots are concentrated and where most of the water is taken up by the plants. The calculation of average root-zone salinity thus overestimates the salinity experienced by the plant.

Most salt-tolerance data were, and are still, collected either in sand culture where the soil water salinity is essentially equal to the irrigation water salinity, or else at high leaching fractions where plant uptake weighted salinity is at most 50% greater than the irrigation water salinity. Also, the simplified calculations utilized do not account for the precipitation of calcite and possibly gypsum that occurs during the concentration of salts in the root zone, nor the nonlinearity between concentration increases and increases in EC and OP.

The combination of the assumption of fixed crop ET with the salt-tolerance calculation from average root-zone salinity estimates or measurements results in overestimation of the quantity of water needed for leaching. The lower the leaching fraction, the greater the discrepancy between average root-zone salinity and plant-uptake weighted salinity. This also explains why drip irrigation systems operated at or near the crop water requirement do not experience measurable yield losses, contrary to predictions based on the application of the leaching requirement concept.

Irrigation recommendations can best be made by using computer simulations of the dynamic processes, considering crop salt tolerance and crop ET and root-zone salinity based on predicted rather than potential water uptake. Letey and Feng (2007), comparing the results of a transient state model to those of a steady state model concluded that the transient model, consistent with field data, indicated that a much lower water application was required to avoid yield loss. Below, we compare the leaching requirements and prediction of yield loss between the SWS (Suarez et al., 2010) and

the Ayers and Westcot (1985) guideline recommendation for leaching and yield loss due to salinity. An analysis of the predicted ET, predicted leaching, and crop yield as related to irrigation water salinity is also presented below.

The user-friendly SWS version (Suarez and Vaughan, 2001; Suarez et al., 2010) of the UNSATCHEM model (Suarez and Simunek, 1997) predicts plant response to water and salt stress under dynamic conditions. The model also predicts soil solution composition as related to variably saturated water and solute transport and chemical processes of adsorption, mineral precipitation dissolution, and cation exchange. The model uses the predicted decreases in plant water uptake to predict the decrease in biomass production. This calculation assumes that yield is directly proportional to water consumption (constant WUE, or water use efficiency):

$$\frac{Y}{Y_M} = 1 - \beta_0 \left( 1 - \frac{ET_a}{ET_p} \right) \quad (3.7)$$

where

$Y$  is the actual yield

$Y_M$  is the maximum yield

$ET_a$  is the predicted or actual ET

$ET_p$  is the potential ET

The parameter  $\beta_0$  is a crop adjustable parameter, which is typically set to 1.0, but varies between 1.0 and 1.3 (Stewart et al., 1977).

Prediction of the yield of individual plant parts (such as seed or fruit) can be obtained by consideration of the relation of reduction in plant water uptake and yield response of the plant part of interest. The model predicted root-zone salinity and relative yield can be contrasted to predictions based on salt stress from guideline predictions.

In the following analysis, we use the SWS model (Suarez et al., 2010) to predict the plant yield reduction from salt stress. A perennial crop with a 100 cm root-zone depth on a loam soil ( $k_s = 25$  cm/d) was irrigated for 200 days. The first irrigation of 11 cm was applied after 10 days. After another 10 days, 22 cm of water was applied over 2 days followed by irrigations of 22 cm every 20 days thereafter for a total of 209 cm of applied irrigation water. The potential ET of the crop for full yield was 200 cm and we assumed a constant potential crop ET ( $ET_p$ ) value of 1 cm/d. The initial soil water and irrigation water composition were that of a predominately NaCl system with lesser quantities of Ca, Mg,  $SO_4$ , and bicarbonate. The  $h_{\phi 50}$  for osmotic stress was set at  $-50$  m, using the equation

$$\alpha_\phi(h_\phi) = \frac{1}{1 + \left( \frac{h_\phi}{h_{\phi 50}} \right)^p} \quad (3.8)$$

where

$\alpha_\phi$  is the osmotic stress response function (scaled from 0 to 1.0, where 1.0 equals no stress)

$h_\phi$  is the calculated osmotic stress

$h_{\phi 50}$  is the model input osmotic stress at which there is a 50% reduction in water use and relative yield

The same scenario was also evaluated using the Ayers and Westcot (1985) procedure. In this calculation, we consider the crop requirement of 200 cm of water and the applied water quantity of 209 cm. The average root-zone salinity was calculated from the average salinity of the root zone, using the irrigation water salinity and the salinity at the bottom of each of the four quarters of the root zone. The salinity in each quarter was based on the assumption that the water uptake is 40% in the first quarter, 30% in the second quarter, 20% in the third quarter, and 10% in the fourth quarter. The average

**FIGURE 3.3** Comparison of SWS model (Ayers and Westcot, 1985; Suarez et al., 2010) predicted crop relative yield as related to irrigation water EC, for a crop with an  $h_{50} = -50$  m ( $-0.5$  MPa),  $ET_p = 200$  cm and 209 cm applied water.

root-zone salinity was thus calculated and converted to OP using the conversion factor  $OP$  (MPa) =  $-0.4$   $EC$  (dS/m), and using Equation 3.8 the stress factor and relative yield was obtained.

The SWS model predicted relative yield as related to irrigation water salinity is shown in Figure 3.3. The model predicts a gradual decline in relative yield with increasing irrigation water salinity. With an irrigation water EC of 4.0 dS/m the relative yield is still at 81%, despite the application of only a small amount of water above the crop potential ET. In contrast, as shown in Figure 3.3, the Ayers and Westcot (1985) calculated yield decreases rapidly above EC 1.5 dS/m. We conclude from the guideline calculations that, for this salt-tolerance data ( $h_{50} = -05$  MPa), irrigation with water above  $EC = 2.0$  dS/m is not feasible for efficient irrigation practices at a leaching fraction of 0.05. As seen in Figure 3.3, at higher irrigation water salinities, there is a dramatic difference between the model and guideline prediction. A similar result to that obtained by calculation from the FAO guidelines (Ayers and Westcot, 1985) would also be obtained using the steady state WATSUIT model (Rhoades and Merrill, 1976).

As shown in Figure 3.4, the guideline assumes constant water consumption even as yield approaches zero. The model predictions show that the decrease in plant water uptake is associated

**FIGURE 3.4** Comparison of SWS model (Ayers and Westcot, 1985; Suarez et al., 2010) predicted leaching fraction as related to irrigation water EC, for a crop with an  $h_{50} = -50$  m ( $-0.5$  MPa) salt-tolerance value,  $ET_p = 200$  cm and 209 cm applied water.

with salt stress, thus, increased leaching with increased salinity of irrigation water. The reduction in water uptake moderates the increase in root-zone salinity. Consideration of the actual water budget is essential for the calculation of the actual salinity in the root zone. The increased leaching and decreased water uptake was due entirely to salt (osmotic stress).

The major discrepancy between these calculations and the SWS predictions is the failure of these calculations to predict the reduction in water consumption by the crop and thus the root-zone salinity and leaching fraction. The leaching fraction was assumed to be 0.043, based on the applied water and crop water demands (ET); however, the SWS model predicted reduced water uptake and a LF = 0.42 at the highest irrigation water salinity examined. The differences between the model predictions (less stress) and the simple calculation method are even greater when we consider waters that precipitate gypsum in the soil, thus reducing the salt concentrations in the soil.

While the above example is somewhat extreme in terms of the close correspondence between water application and crop water demand for full yield (209 cm vs. 200 cm), such irrigation efficiency is not unusual for new irrigation technologies, such as drip irrigation. It appears that dynamic modeling is necessary for irrigation management when low-target leaching fractions are the objective under conditions of potential yield loss due to salinity.

As observed by data collected from drip systems, water applications can be greatly reduced and still maintain yield in most environments. This in turn suggests that less drainage water of higher salinity will be generated, thus disposal for maintaining ground water levels will be reduced.

### 3.4.4 CROP QUALITY AND ECONOMIC CONSIDERATIONS

The classification and consideration of the suitability of saline and brackish waters for irrigation have focused on the threshold of salt-tolerance levels and leaching necessary for full maximum production. As indicated earlier, the leaching needs of current guidelines are excessive. Equally important, such calculations do not consider the farmers objective to optimum profit and the societal need for optimum use of resources. Profitability and societal needs for local food production may make even large decreases in relative yield still feasible, especially when alternative water supplies do not exist. These economic considerations should be inputs to the decisions regarding water use, crop selection, and acceptable yields. Selecting more salt-tolerant crops that do not have projected yield losses may also not be optimal. For example, tall wheatgrass is more salt tolerant than alfalfa; however, alfalfa outyielded tall wheatgrass in controlled studies at EC soil water of 15 dS/m (Grattan et al., 2004).

In some instances, the adverse impacts of reduced yields may be compounded by reduced crop quality such as smaller fruit size, thus decreasing marketability. However, in some instances, crop quality may improve under saline conditions; at least partially offsetting yield reductions. Recently, Grieve (2010) examined the characteristics or composition variables that were improved by salinity for a variety of crops. These benefits include increased sugar content of many crops, including tomato, carrots, onions, and melons, among others. Salt stress may also increase antioxidants and improve fruit flavor and firmness (Grieve, 2010).

### 3.4.5 POTENTIAL FOR INCREASED SALT TOLERANCE

Biotechnology in combination with conventional breeding practices holds great promise to improve salt tolerance, especially of crops that are sensitive or moderately sensitive to salinity. It is generally assumed that the adverse response of plants to elevated concentrations of salt is due to the increased OP of the soil water. The plant is considered to divert energy into extracting low salinity water from the more saline soil water, thus impacting plant growth. However, there is a very wide range in salt tolerance, starting at very low salinity levels such as less than 1.0 dS/m for strawberry. There is strong evidence that specific ion toxicity is the major impact on salt sensitive species.

Munns and Tester (2008) considered that plant response to salinity could be represented by a two part process, with the initial adverse response being related to increased OP and a later response related to specific ion toxicity. They consider that the toxic ion effect dominates for salt sensitive species that lack the ability to control  $\text{Na}^+$  transport, and that for all other plant species the ionic effect is important only at high salinity. Development of salt-tolerant varieties of sensitive species can thus be accomplished by focusing on the development of improved  $\text{Na}^+$  (and to a lesser extent  $\text{Cl}^-$ ) exclusion by the roots and restriction of translocation to the leaves. Additionally, tissue tolerance to salinity by plants is achieved by compartmentalization of  $\text{Na}^+$  and  $\text{Cl}^-$  at the cellular and intracellular level.

### 3.5 CONCLUSIONS

There is very limited potential for using fresh water for increased development of irrigation in arid regions. More realistically, there will be a significant decrease in fresh water use, due to current unsustainable extractions of fresh water. More efficient use of available resources includes use of new irrigation technologies, reuse of drainage water, use of treated municipal waste water, use of brackish water, and reduced leaching for salinity control. However, especially in the presence of rain, the sodicity hazard of lower quality irrigation waters is of concern, since commonly used water quality guidelines may not be sufficiently protective to maintain adequate infiltration. Replacement of current simplified guidelines for leaching with more realistic computer models indicates a decreased need for leaching and will enable better salinity management and use of resources. Opportunities also exist for the development of improved salt tolerance for varieties of salt sensitive plant species.

## 4.1 INTRODUCTION

There is a great deal of information on the behavior of salts in soils and in soil solution suspensions. However, most of this research applies to soils in arid regions, which are often alkaline and consist primarily of 2:1 clay minerals. In temperate regions, soils are often highly weathered, acidic, their mineralogy oxidic, with mixed clay mineralogy (1:1 plus 2:1 clay minerals), and the 2:1 minerals are highly interlayered. There is a need to understand the effects of salts on soils in temperate regions because these soils can become salt-affected from anthropogenic sources. This information is needed by landowners and managers and by state and federal regulatory agencies to protect vital resources.

A salt-affected soil is defined as one that has been adversely affected by the presence or action of soluble salts to the extent that it is no longer suitable for the growth of most crops. This group of soils includes both saline and sodic soils. A saline soil is one that contains an excess of soluble salts, typically  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ ,  $\text{K}^+$ , and  $\text{Na}^+$  and  $\text{SO}_4^{2-}$ ,  $\text{HCO}_3^-$ , and  $\text{Cl}^-$ . A sodic soil possesses an excess of exchangeable sodium. A saline–sodic soil contains both soluble salts and exchangeable Na at levels that impose stress on plant growth (Table 4.1).

Madison, WI.

Salt-affected soils are a common feature of arid and semiarid landscapes because evapotranspiration (ET) exceeds precipitation (P). In humid regions, where  $P > ET$ , soluble salts are leached, but soils may become salt-affected when they are irrigated with brackish water (Kaur et al., 2008) or treated sewage effluent (Leal et al., 2009), intruded by sea water, excessively fertilized with manures (Kuo, 1981; Murphy et al., 2005), or contaminated with oil and gas well brines. Compared to arid and semi-arid regions, detailed studies of salt-affected soils in humid and tropical climate zones are, so far, quite limited (Wongpokhom et al., 2008).

The loss of plant productivity from excess salinity is a worldwide problem. Where salinity is a problem, the effective use and management of salt and water resources dictates the production of agricultural crops. Numerous laboratory and field experiments have been conducted in order to determine the plant growth and yield response to various levels of soil salinity. For example, Shalhevet et al. (1969) found that the yield of peanuts grown in artificially salinized plots was reduced to 50% at EC<sub>e</sub> (specific electrical conductance (EC) of a saturated extract [e]) of 4.7 dS m<sup>-1</sup> and by 20% at EC<sub>e</sub> of 3.8 dS m<sup>-1</sup>. Additionally, these investigators reported that salt tolerance was much higher during germination than during subsequent growth; a comparable 50% reduction in germination did not occur until an EC<sub>e</sub> of 13 dS m<sup>-1</sup>. Shalhevet and Yaron (1973) reported a 10% yield reduction in tomato for every 1.5 dS m<sup>-1</sup> increase in EC<sub>e</sub> above 2 dS m<sup>-1</sup>. The adverse effects of soil salinity on plant growth and productivity vary with the type of plant being grown as well as the type of soil and climate considered. In semi-humid regions of the North China Plain, few effects on tomato plant yield were observed when the irrigation water salinity was increased from 1.1 to 4.9 dS m<sup>-1</sup>. However, higher salinity improved both tomato water use efficiency and irrigation water use efficiency (Wan et al., 2007).

A few studies have examined the effects of soil salinity/sodicity on soil quality as measured by biological processes such as on soil microbial biomass (SMB) and microbial activity (e.g., Sarig et al., 1993; Pathak et al., 1998; Tripathi et al., 2006; Wong et al., 2008). In general, low salinity soils have higher soil respiration rates and lower SMB (Wong et al., 2008). However, available studies often show contradictory results (e.g., Chander et al., 1994; Nelson et al., 1996; Rietz and Haynes, 2003), and in highly saline soils (30 dS m<sup>-1</sup>), the high salt concentration caused elevated SMB as a result of increased substrate availability (Wong et al., 2008). The apparent disparity in trends in respiration and the SMB reported in the literature may be caused by the shifts in the microbial population (from a more active population to a less active one) caused by salinity and/or sodicity (Wong et al., 2008).

Salinity in the soil solution resulting from either indigenous or anthropogenic salt can affect plant growth in three ways (James et al., 1982). It can increase the osmotic potential thus decreasing water potential, thereby reducing water availability, the *osmotic effect*. It can increase the concentration of ions that have an inhibitory effect on plant metabolism, the *specific ion effect*

(James et al., 1982). It can adversely affect soil structure such that water permeability and soil aeration are diminished, the *physiochemical effect*. In many cases, these effects are not mutually exclusive and often overlap in complicated ways.

#### 4.1.1 OSMOTIC EFFECT

Under normal field conditions, the soil–water potential ( $U_w$ ) is determined by the osmotic potential ( $U_s$ ), the matrix potential ( $U_m$ ), and the gravitational potential ( $U_p$ ), such that

$$U_w = U_m + U_s + U_p \quad (4.1)$$

At any given matrix potential and a fixed gravitational potential, an increase in salinity causes a decrease in  $U_w$  (James et al., 1982). Based on the principle that the amount of EC transmitted by a salt solution increases as salt concentration increases. The U.S. Salinity Laboratory Staff (1954) described the relationship as a function of EC,

$$U_s \text{ (bar)} = -0.36 \times \text{EC (dS m}^{-1}\text{)} \quad (4.2)$$

Because the  $U_s$  of a solution is directly related to total dissolved solids (TDS) concentration (Bresler et al., 1982), the relationship can also be expressed as

$$U_s \text{ (bar)} = -5.6 \times 10^{-4} \times \text{TDS (ppm)} \quad (4.3)$$

#### 4.1.2 SPECIFIC ION EFFECT

An excess of Na ions in the soil solution can be inhibitory to plant physiological processes. The sensitivity of plants to Na levels in the soil solution and/or soil surfaces is highly dependent on plant species, as well as plant development stage (Hausenbuiller, 1978; Donahue et al., 1983). Symptoms of Na toxicity can be easily seen when the leaves of sensitive plants contain approximately 0.25% Na on a dry-weight basis (Bresler et al., 1982; James et al., 1982). Sodium toxicity is characterized by leaf tip burn, necrotic spots, and limited leaf expansion, which in turn directly reduces plant photosynthesis and yield (Bernstein, 1975; Neumann et al., 1988).

Other  $\text{Na}^+$  specific ion effects on plant physiological processes are observed when plants are grown in high-Na environments. High sodium concentrations have been shown to increase  $\text{K}^+$  leakage and decrease root elongation in mung bean. Nakamura et al. (1990) reported that when  $\text{Na}^+$  is present in high concentration in the solution, it reduces the transpiration rate of peas (Meiri and Poljakoff-Mayber, 1970) and negatively affects the respiratory pathway of pea roots (Porath and Poljakoff-Mayber, 1964). High  $\text{Na}^+$  concentrations in soil solution also has an antagonistic effect on  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  uptake, causing Ca deficiency symptoms in tomato, pepper, and celery plants (Geraldson, 1957). This was most likely caused by  $\text{Na}^+$  displacing  $\text{Ca}^{2+}$  from membranes of root cells.

#### 4.1.3 PHYSICOCHEMICAL EFFECT

While salinity can be directly detrimental to crop and microorganism growth, it promotes aggregation of soil particles, resulting in structurally stable soils with enhanced permeability and hydraulic conductivity and low susceptibility to shrinking, swelling, and cracking (Mitchell and van Genuchten, 1992; Buckland et al., 2002; Bauder et al., 2008). However, an excess of exchangeable Na, as is the case in sodic soils, is indirectly harmful to plants because it increases clay dispersion, reduces permeability, and causes soil structure to deteriorate.

When soils are negatively charged, the composition of the soil surface (exchanger) is related to the composition of the soil solution. For salt-affected soils, these relationships are described by the exchangeable sodium percentage (ESP) and the sodium adsorption ratio (SAR), such that

$$\text{ESP} = 100 \times \frac{\text{Exchangeable sodium content (cmol}_c \text{ kg}^{-1})}{\text{Cation exchange capacity (cmol}_c \text{ kg}^{-1})} \quad (4.4)$$

and

$$\text{SAR (mmol}_c \text{ L}^{-1})^{0.5} = \frac{[\text{Na}^+]}{[\text{Mg}^{2+} + \text{Ca}^{2+}]^{0.5}} \quad (4.5)$$

where brackets indicates total ion concentration in  $\text{mmol L}^{-1}$ . An empirical relationship between ESP and SAR for soils of the arid Western United States was developed by the U.S. Salinity Laboratory Staff (1954) as

$$\text{ESP} = \frac{100(-0.0126 + 0.014575 \cdot \text{SAR})}{1 + (-0.0126 + 0.014575 \cdot \text{SAR})} \quad (4.6)$$

When SAR is approximately in the range of 10–15, ESP is also in the range of 10–15. In this ESP range, soils of the arid West undergo dispersion and plant growth suffers. However, this relationship does not apply to all soils. For example, a SAR value of 5 was considered to define sodicity for Australian soils (Rengasamy and Olsson, 1991). ESP–SAR relationships can also vary within a soil profile. Mohamed et al. (2008) suggested different regression equations for ESP and SAR for different horizons. Their analyses of more than 90 samples collected in soil profiles from various climatic zones ranging from arid to tropical, revealed that ESP was more variable than SAR in A- and AC-horizons but less variable in C-horizons. However, for simplicity, they proposed a different quadratic equation only for saline and sodic soils. For saline soils,

$$\text{ESP} = 2.855 + 0.73 \cdot \text{SAR} + 0.008 \cdot \text{SAR}^2 \quad R^2 = 0.96 \quad (4.7)$$

and for sodic soils,

$$\text{ESP} = -7.49 + 1.34 \cdot \text{SAR} - 0.0056 \cdot \text{SAR}^2 \quad R^2 = 0.75 \quad (4.8)$$

## 4.2 THERMODYNAMICS OF SODIUM–CALCIUM EXCHANGE IN SOILS

Soils are multicomponent systems consisting of solid (inorganic and organic components), liquid (soil solution), and gaseous phases. These three dynamic phases are to some extent in a constant state of flux, trying to maintain a state of equilibrium. A change in one phase will influence the other two phases until a new equilibrium state is reached. Cation exchange is one type of equilibrium interaction. This involves interchange between cations in the solid phase with other cations in the solution phase.

Cation exchange reactions result from the excess negative charge on soil colloids. There are two types of negative charge in soil systems (Gast, 1977; White and Zelazny, 1986). A permanent negative charge is generated because of isomorphic substitution of elements of smaller positive charge for those of higher positive charge in the crystal structure of clay minerals. Variable negative charge on mineral surfaces and organic matter results from the protonation and deprotonation of surface functional groups (Talibudeen, 1981). The magnitude of the variable negative charge is influenced by pH as well as ionic strength. An increase in pH and/or ionic strength is followed by an increase in negative charge

(Gillman, 1984). In soil systems of temperate regions, these two types of negative charges are always present, but in some soils, one type of negative charge is more dominant than the other.

Because soils contain a mixture of various types of clay minerals and because more than two cations are present in such soil systems (Ca, Mg, K, Na,  $\text{NH}_4$ ), a rigorous theoretical description of ionic distribution is difficult. Several theoretical approaches have been used in deriving binary exchange equations; for salt-affected soils these have been for sodium–calcium exchange. Those most often mentioned in the literature are the thermodynamic and the double layer approaches. The formal thermodynamic approach, based on the mass action principle, gives no direct information about the molecular mechanisms and the forces operating in such systems. On the other hand, the diffuse double layer approach provides a description of Coulombic forces operating on ion exchange processes (Shainberg and Letey, 1984).

#### 4.2.1 SODIUM–CALCIUM EXCHANGE THEORY: MASS ACTION

Various attempts have been used to characterize the relationship between ESP and SAR. The mass action approach is based on the equilibrium established between the chemical potentials of the soil solution and the exchanging surface. The two most common conventions for defining exchanging surface chemical potentials are the Gapon and the Vanselow conventions, with the Gapon convention being more frequently used to characterize salt-affected soils. In the Gapon convention, for the binary chemical reaction

where

X is a cation exchanger taken to have a charge of negative one (–1)

$\text{Na}^+$  and  $\text{Ca}^{2+}$  denote solution species

The Gapon exchange selectivity coefficient is defined as

$$K_G = \frac{[\text{XNa}]}{[\text{XCa}_{1/2}]} \times \frac{[\text{Ca}^{2+}]^{1/2}}{[\text{Na}^+]} \quad (4.10)$$

where

$[\text{Ca}^{2+}]$  and  $[\text{Na}^+]$  are expressed in  $\text{mmol L}^{-1}$

$[\text{CaX}]$  and  $[\text{Na}_2\text{X}]$  are expressed in units of cation exchange capacity (CEC),  $\text{cmol}_c \text{ kg}^{-1}$  or  $\text{meq (100 g)}^{-1}$

Because Ca and Mg behave similarly in soils, the presence of Mg can easily be accounted for as

$$K_G = \frac{[\text{XNa}]}{[\text{X(Ca + Mg)}_{1/2}]} \times \frac{[\text{Ca}^{2+} + \text{Mg}^{2+}]^{1/2}}{[\text{Na}^+]} \quad (4.11)$$

where the exchangeable sodium ratio (ESR) is

$$\frac{[\text{XNa}]}{[\text{X(Ca + Mg)}_{1/2}]}, \text{ or } \frac{[\text{XNa}]}{[\text{XCa}_{1/2}]} \quad (4.12)$$

the ESP is

$$\text{ESP} = 100 \times \frac{[\text{XNa}]}{\text{CEC}} \quad (4.13)$$

and the SAR is

$$\frac{[\text{Na}^+]}{[(\text{Ca} + \text{Mg})]^{1/2}}, \quad \text{or} \quad \frac{[\text{Na}^+]}{[\text{Ca}^{2+}]^{1/2}} \quad (4.14)$$

The Gapon convention has been criticized for lacking thermodynamic rigor and so most quantitative studies of cation exchange phenomenon use the Vanselow convention. Both conventions have been reviewed elsewhere (e.g., Evangelou and McDonald, 1999; Evangelou and Phillips, 2005; McDonald, et al., 2005), as have other conventions (e.g., Essington, 2004).

Bohn et al. (1985) summarized the limitations of most cation exchange equations as follows: (a) Binary cation exchange is frequently considered but rarely the simultaneous presence of additional cations is acknowledged even for highly acidic systems. (b) The cation exchanger is assumed to possess constant cation exchange capacity, but often cation exchange capacity varies with the nature of the exchanging ions, solution concentration, and pH. (c) Simple stoichiometric (1:1) ion exchange is generally assumed, but the apparent deviations from 1:1 stoichiometry are usually explained in terms of simultaneous adsorption of molecules or in terms of the formation of complex ions. (d) Complete reversibility is usually taken for granted.

#### 4.2.2 SODIUM–CALCIUM EXCHANGE THEORY: DIFFUSE DOUBLE LAYER

In the diffuse double layer theory, the fraction of the surface charge neutralized by monovalent ions ( $\sigma_1/\sigma_0$ ) is proportional to SAR and was given as (Erickson, 1952; Bolt, 1955a)

$$\frac{\sigma_1}{\sigma_0} = \frac{\text{SAR}}{31.6\sigma_0\sqrt{\beta}} \sinh^{-1} \frac{31.6\sigma_0\sqrt{\beta}}{\text{SAR} + 126.4u_d\sqrt{\text{Ca}}} \quad (4.15)$$

where

$$\text{SAR} = \frac{n_1^\infty}{\sqrt{n_2^\infty}} \sqrt{1000} \quad (4.16)$$

and

$$\beta = \sqrt{\frac{4e^2}{\epsilon kT}} \quad (4.17)$$

and

$$u_d = \cosh \frac{e\phi_d}{kT} \quad (4.18)$$

where

$e$  is the electronic charge

$\phi$  is the electrical potential as a function of distance ( $d$ ) from the surface

$k$  is Boltzmann's constant

$\epsilon$  is the dielectric constant

$T$  is temperature

$n_1^\infty = \text{Na}$ , and  $n_2^\infty = \text{Ca}$

From Equations 4.15 and 4.16 and recognizing the shape of the function  $y = \sinh^{-1}(x)$ , the following observations can be made. First, increasing SAR increases  $\sigma_1/\sigma_0$ , although not linearly. Second,

increasing ionic strength, which is accounted for by the  $\sqrt{Ca}$  term, decreases  $\sigma_1/\sigma_0$  (Babcock, 1963). And third, increasing CEC ( $-\sigma_0$ ) increases  $\sigma_1$  but decreases  $\sigma_1/\sigma_0$  (Babcock, 1963). All of these observations are consistent with the results of Evangelou and Phillips (1987). Typically it has been assumed that the soil particles were sufficiently far apart so that  $\phi_d = 0$  and  $u_d = 1$  (Bolt, 1955b; Bower, 1959). Shainberg et al. (1980) have shown that in systems where tactoids are formed such that  $\phi_d \neq 0$ , increasing ionic strength increases  $\sigma_1$  for the internal tactoid surfaces but decrease  $\sigma_1$  for the external clay surfaces. This suggests that montmorillonitic soils will behave differently than soils with mixed mineralogy (Arora and Coleman, 1979; Shainberg et al., 1980).

The above equations have implications for ion uptake by plants as well as ion exchange reactions on soil surfaces. Because cell membranes are negatively charged, the presence of an aqueous solution establishes an electric double layer. In many, but not all cases, ion toxicity effects are more closely correlated with ion (concentrations) activities at the membrane surface than with bulk solution ion (concentrations) activities (Kinraide, 1994). In these instances, it is possible to rationalize the effects of ion interactions on ion uptake without invoking the presence of specific ion carriers, multiple sites or other metabolic explanations. For example, Maas (1969) evaluated the effect of increasing concentrations of Li, Na, and K on the uptake of Li, Na, K, and Ca into excised maize roots (Figure 4.1). The results (Figure 4.1) are entirely consistent with the above equations. In Equation 4.16, increasing  $r$  (the relative monovalent ion concentration) increases  $\sigma_1/\sigma_0$ , and hence

**FIGURE 4.1** The effect of increasing  $K^+$ ,  $Na^+$ , and  $Li^+$  concentration on the uptake of  $Ca^{2+}$ ,  $K^+$ ,  $Na^+$ , and  $Li^+$  in 24 h. The concentration of  $Ca^{2+}$  was  $10 \text{ mmol}_c \text{ L}^{-1}$  and the pH was 6. (Redrawn from Mass, E.V., *Plant Physiol.*, 44, 985, 1969. With permission.)

the monovalent ion concentration in the double layer. Accepting that for an ion to move into a cell it must first move to the surface of the cell membrane, increasing the relative monovalent ion concentration in the solution phase necessarily increases ion uptake. When comparing Li, Na, and K, the extent to which ion uptake increases should be proportional to the ability of the ion to move into the Stern layer. That is, increasing the solution phase Li concentration has a modest effect on Li uptake, whereas, increasing the solution K concentration has a large effect on K uptake. The effects of monovalent ion concentration on Ca uptake can be explained similarly. To suppress Ca uptake, the monovalent ion has to compete at the Stern Layer level. Therefore, from Shainberg and Kemper's (1966) analysis one would predict that K would be more effective at suppressing Ca uptake than Li.

### 4.3 EFFECTS OF SOLUTION PROPERTIES ON SODIUM–CALCIUM EXCHANGE

Because single ion activity coefficients are used to quantify ion exchange equilibria (Equations 4.10 and 4.14), any property of a solution that affects these coefficients will affect the resulting equilibria. The single ion activity,  $\{i\}$ , describes the behavior of a particular chemical species in solution as

$$\{i\} = \gamma_i c_i \quad (4.19)$$

where

$\gamma_i$  denotes the single ion activity coefficient

$c_i$  the molar concentration of the chemical species

In ideal dilute aqueous solutions,  $\gamma_i$  equals 1 and the ionic activity equals the molar concentration. In aqueous solutions and in complex nonaqueous solutions,  $\gamma_i$  decreases, as predicted by the Debye–Hückel equation

$$\log \gamma_i = -\frac{Az_i^2 I^{0.5}}{1 + Ba_i I^{0.5}} \quad (4.20)$$

where

$z_i$  is the ionic charge

$a_i$  is the ion size parameter

$I$  is ionic strength

$A$  and  $B$  are two parameters related to the solvent properties and the temperature of the solution

$$A = (2\pi N_A \rho)^{0.5} \left[ \frac{e^2}{4\pi \epsilon \epsilon_0 kT} \right]^{1.5} \quad (4.21)$$

$$B = e_0 \left( \frac{2N_A \rho}{\epsilon \epsilon_0 kT} \right)^{0.5} \quad (4.22)$$

where

$N_A$  is Avogadro's number

$\rho$  is the solvent bulk density

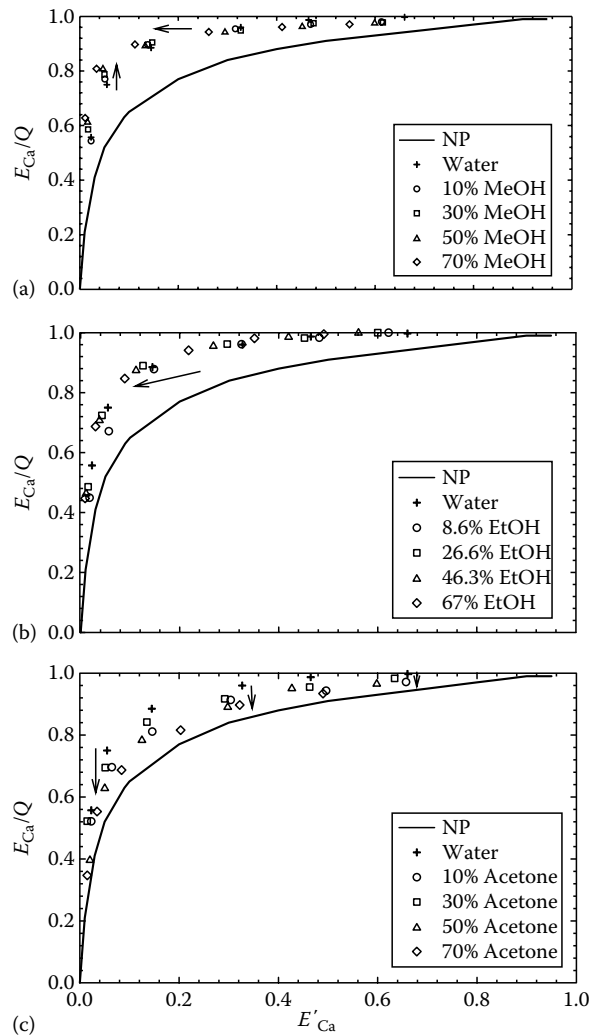

$\epsilon$  is the solvent dielectric constant

$\epsilon_0$  is the permittivity of vacuum

If all variables are kept constant, Equations 4.20 through 4.22 predict that a decrease in  $\epsilon$  would decrease the single ion activity coefficient and, hence, reduces its activity (Equation 4.19). Increasing  $I$  decreases  $\gamma$  for divalent ions more than for monovalent ions.

### 4.3.1 DIELECTRIC CONSTANT EFFECTS

The effects of changing dielectric constant of a solution are demonstrated for calcium–sodium exchange on Wyoming bentonite in methanol, ethanol, and acetone–water systems at 0.03 N Cl and at room temperature (Srou and McDonald, 2005). Calcium–sodium exchange isotherms were plotted at cosolvent concentrations ranging from 0%–70% wt/wt using Ca and Na ionic activities (Figure 4.2). A greater selectivity of bentonite surfaces for Ca ions was observed in all treatments. When compared to water, different trends were observed among and within cosolvents. In methanol–water systems, the preference of bentonite for Ca increased with increased methanol percent at low equivalent Ca fraction (<0.2). At higher Ca fractions, this preference matched that of water. In ethanol–water, no increased preference of the surface for Ca was observed. In acetone–water, increasing cosolvent concentration decreased the preference of the surface for Ca (Figure 4.2). The magnitude of this decrease was greater at low equivalent Ca fraction (<0.2). It is important to note that these isotherms were plotted without

**FIGURE 4.2** Ca–Na exchange isotherms on Wyoming Bentonite at 0.03 N Cl in methanol–water (a), ethanol–water (b) and acetone–water systems (c). (Arrows indicate changes in position of individual data points within and between isotherms.) NP represents nonpreference isotherms in water.  $E_{Ca}$  and  $E'_{Ca}$  are the equivalent fraction of Ca on the exchanger site and in solution, respectively.  $Q$  is the total adsorbed metal charge in  $\text{mol}_e \text{ kg}^{-1}$ . (Reproduced from Srou, R.K. and McDonald, L., *Clays Clay Mineral*, 53(5), 536, 2005.)

accounting for ion pair formation, mainly  $\text{CaCl}^+$ . After correction for  $\text{CaCl}^+$ , both in solution and on the surface (data not shown), the preference of bentonite for  $\text{Ca}^{2+}$  was larger in methanol- and ethanol-water systems. In acetone-water, increased surface preference for Ca was only apparent at low acetone fractions (<50%). At higher acetone fractions, there was evidence of increased Na-loading but no increase in  $\text{Ca}^{2+}$  selectivity.

4.3.2 IONIC STRENGTH AND pH

A large number of studies involving Na–Ca exchange have been conducted with respect to influence of ionic strength and solution composition. Few studies, however, have dealt with the role of pH on Na–Ca exchange reactions. This omission could be due to the fact that most salt-affected soils in the arid and semi-arid West exhibit pH values in the neutral range. Salt-affected soils in temperate regions of the United States are often acid in nature and of mixed type of charge site mineralogy. That is, they are composed of minerals that contribute significant quantities of variable charge.

In order to demonstrate the influence of salt concentration (ionic strength) and soil pH on  $\text{Na}^+$ – $\text{Ca}^{2+}$  exchange on soils representative of humid regions, data on two such soils are given here. These two soils are the Pembroke (fine silty, mixed, mesic, Mollic Paleudalf) from Hardin County, Kentucky, and the Uniontown (fine silty, mixed, mesic, Typic Hapludalf) from Union County, Kentucky (Marsi and Evangelou, 1991a, I). The Pembroke soil is much higher in clay content than the Uniontown soil. The Pembroke soil is dominated by kaolinite and to a lesser extent by mica, vermiculite, and hydroxy-interlayered vermiculite and smectite. The Uniontown soil is dominated by vermiculite and to a lesser extent by mica, kaolinite, and hydroxy-interlayered vermiculite and smectite. Another important difference is the much greater iron content of the Pembroke soil.

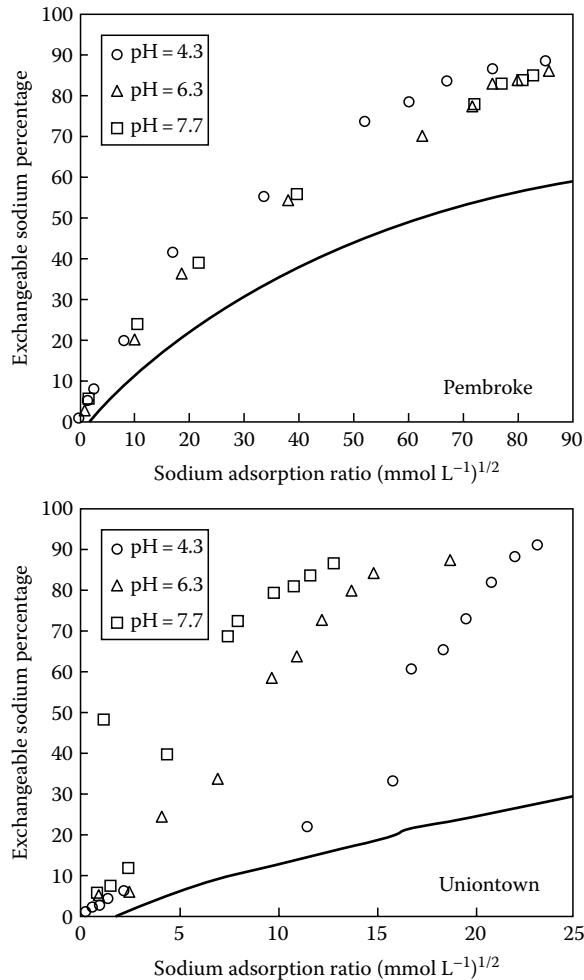

Data in Table 4.2 show the mean value of the summation of exchangeable  $\text{Na}^+$ , ExNa, and exchangeable  $\text{Ca}^{2+}$ , ExCa as a function of pH and chloride concentration for the Pembroke and the Uniontown soils, respectively. Each mean value reported is represented by 15 different ExNa or ExCa loads. The plus or minus value associated with each mean value represents the difference in metal adsorption when one of the metals ( $\text{Na}^+$  or  $\text{Ca}^{2+}$ ) on the exchanger phase approaches zero. Thus for any mean value plus the deviation from the mean, the sum signifies the effective charge ( $\text{EC}_g$ ) of the soil when the latter is loaded with  $\text{Ca}^{2+}$ , and for any mean value minus the deviation from the mean, the difference signifies the  $\text{EC}_g$  of the soil when the latter is loaded with  $\text{Na}^+$ . The data in Table 4.2 clearly demonstrates that the  $\text{EC}_g$  of these two soils is highly ionic strength dependent, specific ion dependent, and to a lesser extent pH dependent. The variation in effective soil charge as a function of the type of metal was previously reported by Fletcher et al. (1984), Hutcheon (1966), and Faucher and Thomas (1954). Murtaza et al. (2001) reported a decrease in the rate of Ca–Na

TABLE 4.2  
Mean – Sum *M* of Exchangeable Na and Ca of Pembroke and Uniontown  
Soils as a Function of pH and Chloride Concentration<sup>a</sup>

exchange (soil sodication) followed by an increase in CEC with increases in pH. In the study by Sreenivas and Reddy (2008), variations in soluble Ca<sup>2+</sup> ion concentrations were negatively correlated to pH and positively correlated to salinity. The two parameters, pH and salinity, were negatively correlated.

The ESP versus SAR plots of the Pembroke soils are presented in Figures 4.3 and 4.4. These two figures demonstrate that the ESP–SAR relationship of the Pembroke soil is independent of pH and ionic strength. The data also imply that the  $K_v$  for this soil should be independent of pH and ionic strength (Evangelou and Phillips, 1987). These data also point out that at low ESP values (ESP < 20) the soil exhibits a high affinity for Na<sup>+</sup>, perhaps because of steric processes. At ESP > 20, no ion preference (Sposito, 1984) is implied. Furthermore, it appears that the Pembroke soil behaves as an ideal exchanger between ESP of about 20 and 100. These observations are consistent with the information presented by van Bladel et al. (1987) and Levy and Hillel (1968).

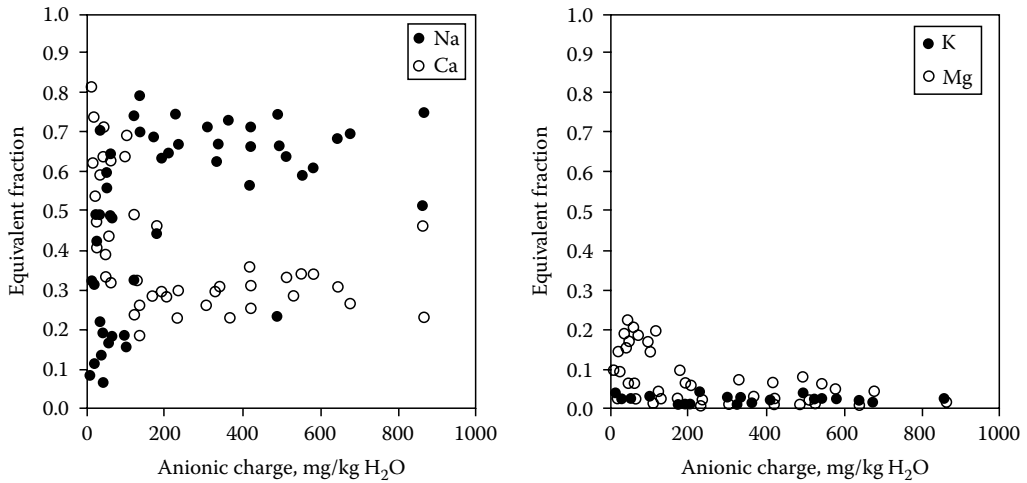

The apparent lack of influence of pH and ionic strength on the selectivity of such soils for either Na<sup>+</sup> or Ca<sup>2+</sup> could be related to a number of processes that take place on a clay surface as pH and/or ionic strength increases. For example, Pratt et al. (1962) have demonstrated on a number of soils that

**FIGURE 4.4** Relationship between ESP and SAR at three chloride (Cl) concentrations of the Pembroke and Uniontown soils at pH 4.3. The solid line without data represents most salt-affected soils in the western United States. (Redrawn from Marsi, M. and Evangelou, V.P., *J. Environ. Sci. Health*, A26(7), 1147, 1991a. With permission.)

as pH decreases the exchange selectivity coefficient of Na<sup>+</sup>–Ca<sup>2+</sup> exchange increases. This increase signifies increase in affinity of the Na<sup>+</sup> by the clay surface through decreasing surface charge density. The data by Pratt et al. (1962) tend to support this conclusion. Additionally, Shainberg et al. (1980) have shown that for Na<sup>+</sup>–Ca<sup>2+</sup> exchange, as ionic strength increases the affinity for Na<sup>+</sup> by the illite surface also increases. The latter observation, however, depends, on whether one deals with an external surface or internal surface. For example, an increase in ionic strength on an external surface (low electric potential surface) could increase the affinity for the Ca<sup>2+</sup>. However, an increase

**FIGURE 4.5** Variation in the equivalent fraction of Na, Ca, K, and Mg adsorbed on the sediment as a function of total dissolved anionic charge. The total range of salinities represented here is from approximately 580–53,000 mg/L. Note the shift from Ca as the predominant adsorbed cation to Na as total dissolved anionic charge increases. (Redrawn from Hanor, J.S., *Appl. Geochem.*, 22(10), 2115, 2007.)

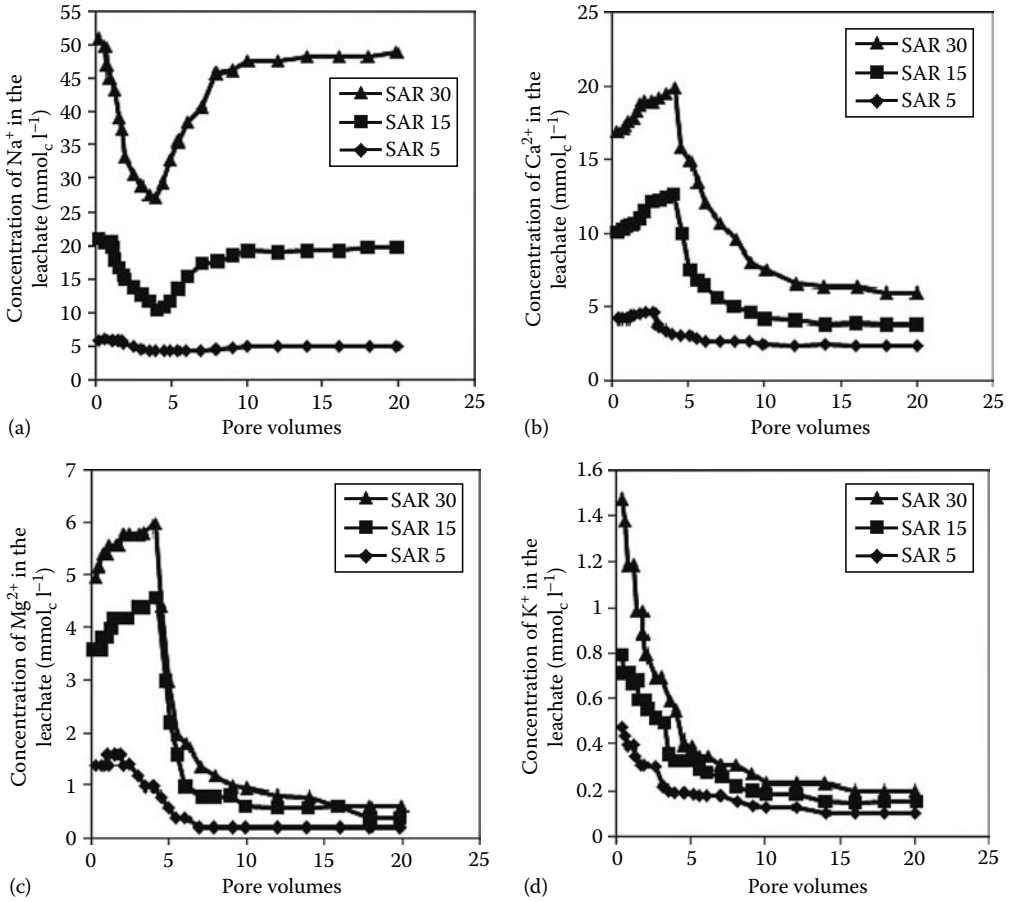

in ionic strength on an internal surface (high electric potential surface) could increase the affinity for the Na<sup>+</sup>. Considering that mixed mineralogy soils are made up of external and internal surfaces, a canceling effect on the magnitude of surface selectivity due to an increase in ionic strength could be obtained.

The ESP versus SAR plots for the Uniontown soil are also shown in Figures 4.3 and 4.4. That pH and ionic strength have a strong influence on  $K_v$  is strongly supported by these figures. As pH and ESP increased, Na<sup>+</sup> is preferred by the solid phase. Stumm and Bilinski (1973) showed that deprotonating clay edge surfaces have greater affinity for a monovalent cation than a divalent cation, because the former (monovalent cation) requires much less free energy to desolvate and thus come closer to the adsorbing surface. On the other hand, according to the data shown in Figure 4.4, as ionic strength increases, the preference of the solid phase for Na<sup>+</sup> decreases. This also implies that under high ionic strength the divalent cations are most likely to carry out the soil deprotonation process. Finally, the data in Figures 4.3 and 4.4 clearly demonstrate that the soils in the two humid regions exhibit a much less affinity for Na<sup>+</sup> than the average salt-affected soil in the western United States. Note the difference in the Na<sup>+</sup> adsorption isotherms exhibited by the humid region soil and the western U.S. soils. This implies that physical behavior and reclamation practices for these two groups of soils are expected to be different.

Hanor (2007) studied the effects of salinity (ionic strength) on the composition and partitioning of adsorbed cations onto clays from brine-contaminated soil samples from the siliciclastic sediments in Southern Louisiana. At low salinities (<1200 mg L<sup>-1</sup>), Ca and Mg dominated as adsorbed cations. At moderate to high salinities (up to 53,000 mg L<sup>-1</sup>), adsorbed sodium was dominant (Hanor, 2007). The relationship between the proportions of adsorbed cations salinity followed a nonlinear pattern and the transition from Ca- to Na-dominated adsorption occurred over a narrow range of salinities (Figure 4.5).

### 4.3.3 SODIUM CONCENTRATION EFFECTS

In sandy soils, the application of three types of irrigation waters with corresponding SAR values of 5, 15, and 30 resulted in the displacement of cations (Ca<sup>2+</sup>, Mg<sup>2+</sup>, and K<sup>+</sup>) and anions into solution and their replacement by Na<sup>+</sup>. Figure 4.6 shows the breakthrough curves for Na<sup>+</sup>, Ca<sup>2+</sup>,

**FIGURE 4.6** Breakthrough curves for (a) Na<sup>+</sup>, (b) Ca<sup>2+</sup>, (c) Mg<sup>2+</sup>, and (d) K<sup>+</sup> in soil leached with different SAR solutions. (Redrawn from Jalali, M. and Merrihpour, J., *Environ. Geol.*, 53, 1289, 2008.)

Mg<sup>2+</sup>, and K<sup>+</sup>. In Figure 4.6a, the concentration of effluent Na<sup>+</sup> decreased sharply to a minimum of about 4, 10.2, and 27 mmol<sub>c</sub> L<sup>-1</sup> for SAR 5, 15, and 30, respectively and reached input concentrations after about 15 pore volumes of leachate passed through the columns in all solutions. This decrease in effluent Na<sup>+</sup> concentration was accompanied by an increase in effluent Ca<sup>2+</sup> (Figure 4.6b) and Mg<sup>2+</sup> (Figure 4.6c) concentrations, probably resulting from the displacement of soil indigenous exchangeable Ca<sup>2+</sup> and Mg<sup>2+</sup> by leachate Na<sup>+</sup>. These peaks of displaced Ca<sup>2+</sup> and Mg<sup>2+</sup> were followed by sharp reduction in effluent concentrations, indicating slow release of both cations to soil solution and after about 20 pore volumes, reached approximately input values (Figure 4.6b and c). Leaching of Ca<sup>2+</sup>, Mg<sup>2+</sup>, and K<sup>+</sup> from soils subjected to irrigation with poor quality water presents a significant loss of valuable plant nutrient. In all treatments, effluent K<sup>+</sup> concentrations were drastically reduced and reached constant values after about five pore volumes of leachate (Figure 4.6d). After 20 pore volumes, the concentration of leached K<sup>+</sup> remained below 0.2 and 0.1 cmol<sub>c</sub> L<sup>-1</sup> for SAR 30 and 5, respectively (values above the water quality standards). An increase in K<sup>+</sup> leaching is therefore expected to increase K<sup>+</sup> concentrations in groundwater in agricultural areas (Jalali and Merrihpour, 2008). Also, increasing the level of SAR from 5 to 15 and 30 corresponded to an increase in the average ESP of the soil from 10.4 to 20.3, and 32.5, respectively (Figure 4.7), and resulted in dispersion of soil aggregates and reduction in soil permeability (Jalali and Merrihpour, 2008).

**FIGURE 4.7** Changes in average ESP as a function of pore volumes when soil was leached with different SAR solutions. (Redrawn from Jalali, M. and Merrikhpour, J., *Environ. Geol.*, 53, 1289, 2008.)

#### 4.4 SODIUM INFLUENCE ON SOIL DISPERSION AND SATURATED HYDRAULIC CONDUCTIVITY

When the amount of exchangeable  $\text{Na}^+$  relative to exchangeable  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  exceeds a critical threshold, there can be deleterious effects on physical properties of soil. Due to its large size and single charge, the adsorption of the hydrated  $\text{Na}^+$  ion into the diffuse double layer around the clay platelets cause them to separate (Curtin et al., 1994). This physical separation of clay platelets causes modification of soil pore distribution, results in high swelling pressure, and creates single clay platelets that persist in solution and/or are carried by water and deposited in soil pores (So and Aylmore, 1993; Mace and Amrhein, 2001). Clay dispersion in turn affects soil hydraulic conductivity. An increase in Na levels in the soil solution or on exchanging surfaces causes soil-saturated hydraulic conductivity to decrease (Russo and Bresler, 1977; Agassi et al., 1981; Kazman et al., 1983).

Soils disperse only when they are in equilibrium with an electrolyte solution concentration under the “flocculation value.” The flocculation value depends on SAR, solution ionic strength, clay mineralogy (El-Swaify, 1976), and pH (Keren et al., 1988). For example, flocculation values for Na/Ca–montmorillonite were 3, 4, and 7  $\text{mmol}_c \text{L}^{-1}$  and 6, 10, and 18  $\text{mmol}_c \text{L}^{-1}$  for Na/Ca–illite with ESP values of 5, 10, and 20, respectively (Shainberg and Letey, 1984). Under tropical conditions, irrigation with treated sewage effluents resulted in average increases of exchangeable sodium from 2.4 to 5.9  $\text{mmol}_c \text{kg}^{-1}$ , soluble Na from 1.4 to 4.7  $\text{mmol L}^{-1}$ , and SAR of soil solution from 3.6 to 12.6 ( $\text{mmol L}^{-1})^{1/2}$  in the soil profile (Leal et al., 2009). The increasing levels in these sodicity parameters resulted in significant increases in ESP and in clay (mostly kaolinite) dispersion rates (Figure 4.8). Based on these results, it was suggested that the negative effects of high SAR solutions on kaolinitic soils are more pronounced compared to the montmorillinitic soils of arid and semi-arid regions (Leal et al., 2009). Also, these soils are expected to have higher sensitivity to small increases in exchangeable Na and pH due to the presence of organic matter adsorbed to kaolinitic edges. This condition can result in the reversion of positive charges to negative charges and lead to the inhibition of the dominant edge-face flocculation (Leal et al., 2009 and references therein).

The classic theory of colloidal stability developed by Derjaguin and Landau (1941) and Verwey and Overbeek (1948) (DLVO theory) generally accounts for the influences of ion valence and concentration on suspended colloid interactions. According to the DLVO theory, the long-range

**FIGURE 4.8** Mean exchangeable sodium percentage (a) and mean percent clay dispersion (b) in the soil profile (0–100 cm) before and after TSE irrigation between the different irrigated treatments (T100, T150, and T200). Control, without TSE irrigation, and T100, T150, T200 corresponding to TSE irrigation supplying 100%, 150%, and 200% of the crop water demand, respectively. 0 month represents soil conditions prior to sugarcane planting and irrigation and 16 months correspond to soil conditions after 16 months of TSE irrigation. (Redrawn from Leal, R.M.P. et al., *Agric. Water Manage.*, 96(2), 307, 2009.)

repulsive potential resulting from diffuse double layers (DDLs) of like charged colloids retards the coagulation or flocculation rate of clay colloids.

Colloidal stability (maximum dispersion) depends on maximum  $\Phi$  ( $\Phi_{\max}$ ), which describes the maximum repulsive energy between two planar colloidal surfaces. Furthermore,  $\Phi_{\max}$  is controlled by surface electric potential ( $\Psi$ ) and ionic strength. The component,  $\Psi$ , is controlled by the pH of the colloidal suspension, assuming that the colloids exhibit pH-dependent charge (Uehara and Gillman, 1980). Generally, in clay colloids, on increasing pH,  $\Psi$  becomes more negative and thus  $\Phi_{\max}$  increases. Conversely, on decreasing pH,  $\Psi$  becomes less negative. When  $\Psi$  approaches zero,  $\Phi_{\max}$  approaches zero. This leads to colloid coagulation or flocculation (Emerson, 1964; Tama and El-Swaify, 1976; Singh and Uehara, 1986; Keren and Singer, 1988). Increasing  $I$  in a colloidal suspension decreases  $\Phi_{\max}$ , which enhances colloid flocculation rate (Emerson, 1964). Nasser and James (2008) demonstrated that at pH < 7 and regardless of electrolyte concentration, kaolinite-NaCl dispersions were highly flocculated with strong edge–edge interactions. Higher pH values and low electrolyte concentrations caused the flocculated structure of kaolinite to breakdown, whereas high electrolyte concentrations produced randomly structured flocs. Ahmad and Karube (2001) showed that the critical coagulation concentration (CCC); a threshold concentration between dispersion and coagulation that is comparable to the flocculation value and expressed in units  $\text{mol}_c \text{ kg}^{-1}$  of a montmorillonite clay decreased with decreasing pH (Figure 4.9). In NaCl, CCC decreased slightly as pH decreased from 10 to 7, sharply between pH 7 and 6, and then moderately as pH decreased from 6 to 3 (Figure 4.9). Similar CCC values were measured at pH below 6.5 in NaCl, KCl, and  $\text{NH}_4\text{Cl}$  solutions. At pH = 9, CCC followed the order of hydrated ion radius ( $\text{Na} > \text{K} > \text{NH}_4$ ). Also, the investigators (Ahmad and Karube, 2001) demonstrated that montmorillonite dispersed at low SAR value (below 13) when EC was less than a threshold value.

In addition to these components ( $\Psi$ ,  $I$ ) controlling colloidal flocculation or stability (Schofield and Samson, 1954; Evangelou, 1990; Shainberg and Letey, 1984), additional components in the case of clay colloids are also involved. These additional components include relative proportion of monovalent to divalent cations in the bulk solution (Shainberg and Letey, 1984), type of cations, shape of particles and initial particle concentration in suspension (Oster et al., 1980), type of clay minerals present, and relative proportion of clay minerals (McBride, 1981).

**FIGURE 4.9** Dispersion and coagulation of montmorillonite in NaCl solution at different pH. (Redrawn from Ahmad, M.M. and Karube, J., *Pak. J. Soil Sci.*, 20(4), 75, 2001.)

The above observations of the effect of clay mineral type and their relative proportion on dispersion and flocculation behavior suggest that certain interactions between the various colloids change their dispersive behavior or colloidal stability. Based on these observations, soils of mixed mineralogy and with various proportions of different clay minerals are expected to have unique dispersive properties.

Many processes and/or conditions in the soil environment are highly dependent on colloid dispersion or flocculation. Such processes and/or conditions include erosion, water suspension of solids, soil structure, and hydraulic conductivity, among many others. A number of studies involving sodic soils have been carried out in order to relate soil dispersive properties to saturated hydraulic conductivity. For example, Suarez et al. (1984) was able to link soil dispersion in suspensions measured spectrophotometrically to saturated hydraulic conductivity. Others researchers measured the percentage of clay in suspension (dispersion index) versus saturated hydraulic conductivity. The purpose in establishing clay dispersion–saturated hydraulic conductivity relationships is to develop rapid tests for predicting hydraulic conductivity of salt-affected soils and/or to evaluate mechanisms that are involved in regulating saturated hydraulic conductivity.

The data in Figure 4.10 show that the potential of soils to undergo dispersion is related to ESP. This is true only at low ionic strengths. When ionic strength was adjusted to 200 mmol L<sup>-1</sup>, there appears to be no effect of ESP on soil dispersion due to suppression of the double layer repulsive forces. These data are consistent with qualitative predictions of clay dispersion equations (Marsi and Evangelou, 1991b). The data in Figure 4.11 also show that, even at pH 4.3, both soils exhibit dispersion at low ionic strength. This observation suggests that at pH 4.3 both of these soils will likely exhibit a net negative charge.

It can be summarized from Figures 4.10 and 4.11 that the Uniontown soil was more sensitive to dispersion under decreasing electrolyte concentration and increasing ESP but less sensitive to pH changes than the Pembroke soil. The data also demonstrate that for any given electrolyte concentration, pH, and ESP, the dispersion index of the Uniontown soil was always greater than that of the Pembroke soil. This appeared to be in agreement with the thermodynamic exchange parameter of these soils. The magnitude of adsorbed ion activity coefficient  $f_{Na}$  for the Uniontown soil is greater

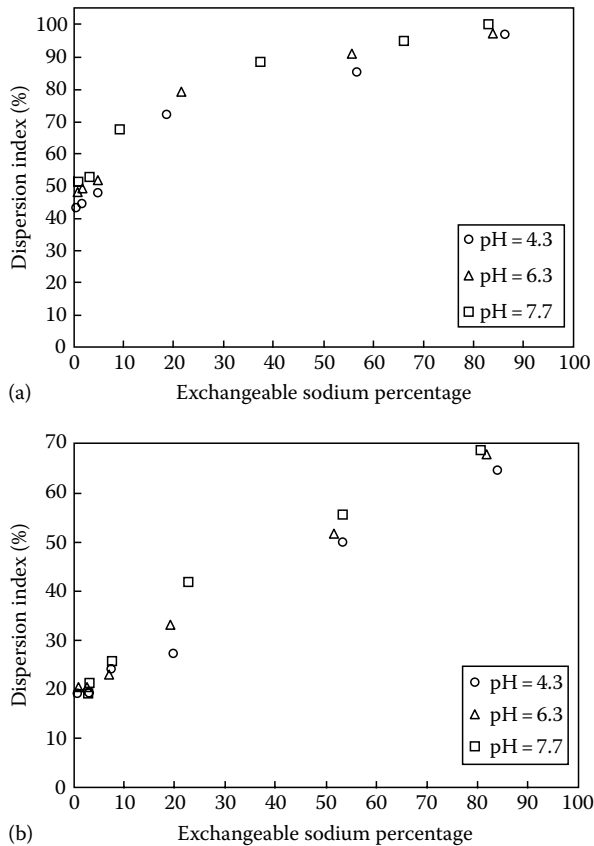

**FIGURE 4.10** Influence of ESP on the DI of the Pembroke (a) and Uniontown (b) soils near pH 4 and at three chloride (Cl) concentrations. (From Marsi, M. and Evangelou, V.P., *J. Environ. Sci. Health*, A26(7), 1177, 1991b. With permission.)

than 1 (data not shown). Considering that  $f_{Na} > 1$  could signify that  $Na^+$  “reside” in the diffuse layer, one expects the Uniontown soil to be highly dispersive. On the other hand, the magnitude of  $f_{Na}$  for the Pembroke soil is less than 1 (data not shown). Assuming this signifies that  $Na^+$  forms outer-sphere complexes with the clay surfaces, this soil would be expected to be less dispersive than the Uniontown.

The presence of exchangeable  $Na^+$  significantly decreases soil permeability (Quirk and Schofield, 1955; Reeve and Bower, 1960; Park and O’Connor, 1980). The mechanism(s) responsible for decreasing soil permeability in the presence of  $Na^+$  can be demonstrated by looking into the components controlling water or soil solution movement potential under saturating conditions.

Soil-saturated hydraulic conductivity is described by Lagerwerff et al. (1969) as

$$K = \frac{kg}{\eta} \tag{4.23}$$

**FIGURE 4.11** Influence of ESP on the DI of the Pembroke (a) and Uniontown (b) equilibrated with a solution of 5 mmol L<sup>-1</sup> chloride (Cl) at three pH values. (From Marsi, M. and Evangelou, V.P., *J. Environ. Sci. Health*, A26(7), 1177, 1991b. With permission.)

where

- $k$  is the permeability of the soil
- $g$  is the gravitational constant
- $\eta$  is the kinematic viscosity or the ratio of solution viscosity to fluid density

For soil systems contaminated with brackish solutions, kinematic viscosity is not significantly affected (Lagerwerff et al., 1969) and thus the components controlling water flow viscosity are the hydraulic gradient ( $H$ ) and soil permeability ( $k$ ). The latter component ( $k$ ) is influenced by clay dispersion and migration, and clay swelling. These processes may cause considerable alteration to soil matrix characteristics, such as porosity, pore-size distribution, tortuosity, and void shape (Cass and Sumner, 1982). A detailed description of the physicochemical mechanism influencing clay dispersion and/or clay swelling is given in Marsi and Evangelou (1991b).

The deterioration of soil physical properties influencing  $k$  is accelerated directly or indirectly by the presence of high Na<sup>+</sup> on the soil's exchange complex and the electrolyte composition and concentration of the soil solution (Quirk and Schofield, 1955; McNeal and Coleman, 1966, Rowell et al., 1969; Hamid and Mustafa, 1975; Yousaf et al., 1987). To improve soil physical properties of Na-affected soils, Ca<sup>2+</sup> is usually added to replace the Na<sup>+</sup> on the exchange sites. Calcium reduces clay swelling and enhances clay flocculation (Greacen, 1959).

Additional components influencing the effect of Na<sup>+</sup> on saturated hydraulic conductivity of soil include clay mineralogy, clay content, soil bulk density, Fe and Al oxide content, organic matter

content, salt concentration, and  $\text{Na}^+/\text{Ca}^{2+}$  ratio (Gardner et al., 1959; McNeal et al., 1968; Shainberg and Casserman, 1971; Frenkel et al., 1978; Cass and Sumner, 1982; Keren and Singer, 1988; Keren et al., 1988; Wada and Beppu, 1989). The hydraulic properties of soils dominated by 1:1 type clay mineralogy (i.e., kaolinite) and Fe and Al oxides are relatively insensitive to variations in soil solution composition and concentration in contrast to those dominated by 2:1 type clay minerals (i.e., montmorillonite). McNeal and Coleman (1966) stated that each soil has a unique saturated hydraulic conductivity response threshold because of its unique properties. Pal et al. (2006) suggest the use of saturated hydraulic conductivity of less than  $10\text{ mm h}^{-1}$  (weighted mean in 0–100 cm depth of soil) as a robust criterion instead of any ESP or SAR values.

Martin et al. (1964) studied the importance of pH on saturated hydraulic conductivity (SHC) and found that the same total quantity of  $\text{Na}^+$  on a soil will reduce SHC more effectively at a lower pH than at a higher pH. These investigators (Martin et al., 1964) concluded that the reduction in soil CEC as pH decreased was responsible for decreasing soil SHC, since the same amount of  $\text{Na}^+$  represents a greater ESP at a lower soil pH. Suarez et al. (1984) reported that for the same ESP or SAR value, the SHC decreased as pH increased. The pH effect on hydraulic conductivity is pronounced only when the soil contains a high quantity of variable-charge minerals and organic matter.

In contrast to the studies on the effect of the electrolyte concentration and composition on saturated hydraulic conductivity, fewer studies examined the influence of pH, solution composition, and salt concentration on SHC. It seems necessary to understand the influence of pH on soil hydraulic conductivity, because soils contaminated with oil well brine in humid regions are often associated with low pH; either pH drifts downward as extensive leaching is taking place or the pH rises when alkaline brines are discharged onto the soil.

Reductions in the relative saturated hydraulic conductivity (RSHC) as a function of pH and chloride concentration are summarized in Table 4.3. These data show “threshold” ESP or SAR values which are defined as 20% relative reduction in RSHC. It is clearly shown that the ESP–SAR critical threshold is highly dependent on pH and Cl concentrations. It varies from an SAR of approximately 0.30 to SAR of approximately 90. These values strongly indicate that the critical SAR threshold reported by the U.S. Salinity Laboratory Staff (1954), in the range of 10–15, applies to the  $50\text{ mmol L}^{-1}$  Cl concentration of the Uniontown soil only. The Pembroke soil (Table 4.3) at the  $50\text{ mmol L}^{-1}$  Cl concentration exhibits a more critical threshold.

The data presented in Table 4.3 show that the RSHC of the Uniontown soil is more sensitive to ionic strength and solution composition than that of the Pembroke soil. These sensitivity differences are probably a result of the differences in mineralogy between the two soils. The effect of clay mineralogy on the critical SAR was also reported by McNeal and Coleman (1966).

**TABLE 4.3**  
**SAR<sup>a</sup> and ESP Values Associated with 20% Reduction in RSHC for Pembroke and Uniontown Soils at Three pH Values**

| Cl (mmol L <sup>-1</sup> ) | Pembroke       |      |        |     |        |     | Uniontown      |      |        |     |        |      |

<sup>b</sup> Threshold values are not reported because the reduction on SHC is less than 20%.

4.4.1 IMHOFF CONE-SATURATED HYDRAULIC CONDUCTIVITY

Values of RSHC correlated with Imhoff cone results, expressed as dispersion index (DI) to predict the RSHC for the soils, when salt affected, are shown in Figures 4.12 and 4.13.

Figure 4.12 demonstrates that for each of the two soils there was a unique RSHC–DI relationship at the 5 mmol L<sup>-1</sup> chloride concentration. More importantly, at this Cl concentration a lower DI was needed than with the higher Cl concentrations to suppress to a large degree the RSHC. This suggests that at the lower salt concentration, clay swelling is also implicated in reducing RSHC (Quirk and Schofield, 1955; McNeal and Coleman, 1966; McNeal et al, 1966; Rowell et al., 1969; Keren et al., 1988). In Figure 4.13, the slope of the RSHC–DI relationship was greater for the Pembroke soil than the Uniontown soil. This suggested that the RSHC of Uniontown soil was less affected by changes in DI than was the Pembroke soil. Moreover, these data also show that to attain similar relative suppression in RSHC, a greater DI was needed for the Uniontown soil than the Pembroke soil. This is probably due to soil texture. The Pembroke soil contained 59% clay, whereas the Uniontown contained only 28%. Hamid and Mustafa (1975) reported that RSHC–DI relationships are highly affected by soil texture as well as pore size distribution. It is also implied in

**FIGURE 4.12** Relationship between RSHC and DI of the Pembroke soil at pH 7.5 (a) and Uniontown soil at pH 7.7 (b) with three chloride (Cl) concentrations. (From Marsi, M. and Evangelou, V.P., *J. Environ. Sci. Health*, A26(7), 1195, 1991c. With permission.)

**FIGURE 4.13** Relationship between RSHC and DI of the Pembroke and Uniontown soils equilibrated with three chloride (Cl) concentrations at three pH values (DI = amount of dispersed clay divided by the amount of clay in 1 g soil). (From Marsi, M. and Evangelou, V.P., *J. Environ. Sci. Health*, 1991c. With permission.)

Figure 4.13 that as pH increases, a small DI imposes a large suppression in the RSHC. The increase in pH could be implicated in increasing swelling potential. This is likely because of the removal of Al-OH polymers from the interlayer (Figure 4.14). The presence of Al-OH polymers at the lower pH values may limit interlayer swelling (Barnhisel, 1977). Clays that have the basic 2:1 mineral structure may exhibit limited expansion because of the presence of hydroxy-Al islands which block their interlayer spaces (Figure 4.14). It is well known that these Al interlayer components are completely removed at pH values 9.0–10, through dissolution mechanisms (Keren, 1980). This interlayer removal is expected to increase the dispersion potential of the mineral by allowing free expansion. Similar phenomena of hydroxy-Al interlayer removal have been demonstrated to be the cause for failed septic systems (Zelazny et al., 1980), under a far less dramatic chemical regime than that often encountered in salt brine-contaminated systems. In addition to increased swelling, dispersion can also be enhanced in such systems as a result of the increased mineral surface charge following removal of Al-hydroxy from the interlayer. When removed from interlayer positions, these positively charged hydroxyl-Al components would increase the effective surface charge available for Na adsorption, thus increasing the probability of soil structural destabilization.

In conclusion the DI could predict RSHC. The relationship between RSHC and DI is not universal; however, it is unique to a particular soil under a given set of leaching conditions. The properties that appear to influence the RSHC–DI relationship of soils in humid regions are soil mineralogy, soil texture, soil pH, ionic strength, and solution composition. Information on humid region soils clearly demonstrates the following points: (1) the RSHC is related to the clay DI,

**FIGURE 4.14** Al-OH polymer removal from the interlayer space of 2:1 clay.

(2) the relationship between RSHC and DI is dependent upon ionic strength and pH; and (3) soils exhibit different RSHC–DI relationships. Furthermore, soils of the humid regions appear to behave differently with respect to  $\text{Na}^+$ – $\text{Ca}^{2+}$  exchange and physical stability in relationship to soils of arid regions.

4.5 ASSESSMENT OF SALINITY AND SODICITY

Different methods have been developed to identify, map, and monitor saline and sodic soils: (a) remote sensing, (b) solute transport modeling, and (c) geophysics. Other techniques such as spectroscopy (namely XRD, thin section microscopy, and SEM-EDS) have also been applied to recognize the presence and abundance of salt in soils (Farifteh et al., 2008; Wongpokhom et al., 2008).

4.5.1 REMOTE SENSING

Remote sensing data and technology have been widely used to map severely salt-affected areas (Goetz and Herring, 1989; Mougenot et al., 1993; Ben-Dor, 2002; Dehaan and Taylor, 2003). Compared to other methods of soil salinity assessment, remote sensing techniques save time, labor, and effort (Robbins and Wiegand, 1990). Remote sensors are of three types: (a) ground-based, (b) air-borne, and (c) space-borne. Air-borne and/or space-borne remotely sensed data are generally complemented with field measurement to determine the relations between spectral signature and soil surface properties (Figure 4.15).

An example of ground-based sensors is the spectroradiometers such as the GER3700 and FieldSpec FR (ASD). These instruments measure the reflectance spectra of salt-affected soils in narrow and continuous spectral bands, which are then analyzed using regression (monovariate, multivariate, and/or partial least squares) analyses and compared to pre-established minerals and salt crusts to identify and quantify salinity in salt-affected areas (Drake, 1995; Howari et al., 2002; Farifteh et al., 2004).

Airborne sensors such as AVIRIS provide high spectral and spatial resolution imageries that have been successfully used, in combination with field measurements, to map salt-affected areas with different degrees of severity (Chaturvedi et al., 1983; Taylor et al., 1996; Metternicht, 1998; Taylor and Dehaan, 2000; Ben-Dor, 2002; Dehaan and Taylor, 2002; Metternicht and Zinck, 2003). To identify saline soils, the collected radiance values are converted to reflectance values of the land surface (Clark et al., 2002). Space-born sensors provide global coverage of the earth’s surface

**FIGURE 4.15** Image classification of salt-affected soils using thematic mapper (TM) images (CSIRO, Canberra, Australian Capital Territory, Australia). (From Farifteh, J. et al., *Geoderma*, 145(3/4), 196, 2006.)

conditions at different spatial and temporal resolutions. The application of broadband remote sensing (e.g., Landsat, SPOT, Aster) in salinity studies has been limited due to spatial and spectral resolution problems that mask detailed spectral signatures (Cloutis, 1996). Spectral data are often integrated with GIS (Geographic Information Systems) and spatial statistics to map and model the spatial distribution of salinity (Chong et al., 2001; Khan et al., 2001).

Metternicht and Zinck (2003) have critically reviewed the potentials and limitations of the application of remote sensing technology to the assessment of soil salinity. Remote sensors have been successfully used to detect very saline soils (Eldiery et al., 2005; Farifteh et al., 2006). The potential for remote sensing technology to recognize different degrees of soil salinity and/or sodicity is limited despite recent attempts by Bannari et al. (2008) to apply advance land imaging (EO-1 ALI) sensor spectral bands to discriminate between slightly and moderately saline soils. Remote sensors are unable to detect salt distribution in the near-surface or subsurface soils. Sensors are only able to scan the soil surface. Because the entire soil profile is involved in the salinization process and management, other solute transport modeling and geophysical techniques should also be used.

#### 4.5.2 SOLUTE TRANSPORT MODELING

Modeling solute transport provides spatial and temporal information on the movement of salt through the soil profile (Schoups and Hopmans, 2002). Solute transport modeling combines computer modeling, geostatistics, and field measurements (Jolly et al., 1998). Both mathematical and geopedologic models (e.g., Pishkar, 2003) have been used to study the mechanisms of solute transport in the vadose zone (Farifteh et al., 2006 and references therein). Other approaches have used transfer functions models to predict average values of solute concentration (as a function of depth and time) through highly variable field systems (Jury, 1982). El-Kadi et al. (1994) combined GIS with a numerical model to study solute transport in the geosphere.

#### 4.5.3 GEOPHYSICS

Geophysical methods are generally accepted as the most effective methods for the detection of soil salinity (Norman et al., 1988). Geophysical techniques are noninvasive and have been efficiently used to identify salinity in cropped land. A major advantage of geophysical technology is its ability

**FIGURE 4.16** Apparent conductance image of the Toolibin catchment. (From Farifteh, J. et al., *Geoderma*, 145(3/4), 196, 2006.)

to detect near-surface and subsurface salinity (Howlett et al., 2001). However, these technologies are expensive, time consuming, and require considerable human resources.

Geophysical instruments can be ground-, air-, and borehole-based instruments. Ground-based instruments are the most commonly used and are either electromagnetic (EM) conductivity meters or contact electrodes. Both instruments measure the apparent conductivity of soils ( $EC_a$ ) (Figure 4.16). This conductivity depends on salt concentration and type, clay content, soil moisture, and soil porosity. Applications of EM series instruments and their efficiencies in soil salinity assessments include the studies of Williams and Fiddler (1983), Rhoades et al. (1989), and Lesch et al. (1995). Paine et al. (2007) combined multifrequency EM induction spectral images with surface water chemical analysis to identify stream segments that receive saline flow in a small Texas coastal-plain basin.

#### 4.6 RECLAMATION OF SALT-AFFECTED SOILS

The removal of sodium from the soil profile of any given salt-affected soil is necessary, because Na is one of the most pronounced ions that influences plant growth and yield in salt-affected soils (Hoffman et al., 1983). Sodium is not only toxic to most plants because of its specific ion effect but it also influences certain soil properties. The major concern is the eventual deterioration of soil structure, resulting in decreased water infiltration and gas exchangeability (Bresler et al., 1982).

Management and reclamation of salt-affected soils are necessary to maintain, or increase, their productivity. At least three processes take place during reclamation of a sodic soil: (a) the  $Na^+$  on the exchange complex is replaced by  $Ca^{2+}$ ; (b) the soil-saturated hydraulic conductivity is improved following Ca application; and (c) sodium salts are removed from soil profile through leaching (James et al., 1982). Thus, reclamation of salt-affected soils often requires the removal of excess soluble salts as well as reduction of the soil ESP (see Oster and Frenkel, 1980 and references therein). The only proven method to reduce the soluble salt concentration in the root zone is through leaching. Reduction of the ESP is more difficult, because sodium ions adsorbed on exchange sites must first be replaced with divalent cations and then be leached from the root zone. According to Hoffman et al. (1983), the amount of leaching required is dependent on the salt content of irrigation water, salt tolerance of the crops, climatic conditions, and soil and water management practices.

Agromelioration is the approach of reclaiming saline and/or sodic soils in which the application of chemical amendments (such as hydrochloric acid, sulfuric acid, gypsum, etc.) is minimized and is compensated by agronomic practices (Zaka et al., 2003). In this approach, a starter dose of chemical amendment is added to bring the level of salinity/sodicity in the root zone of the salt-affect soil to a level within the tolerance limits of the crop. Further reclamation is obtained through leaching and cultural practices such as the application of organic matter. Theoretically, the addition of organic matter to saline soils of low CEC increases CEC and promotes the aggregation of soil particles. As a result, leaching is improved (Murtaza et al., 2001). Hussain et al. (2001) found that combining three amendments (gypsum, sulfuric acid, and farmyard manure) significantly decreases SAR of sodic soils and improves soil conditions (decreases bulk density, increases porosity, water permeability, and hydraulic conductivity). In another study by Kaur et al. (2008), the application of gypsum and organic matter (farmyard manure and green manure) decreased pH, EC, SAR, bulk density, and ESP and increased the water infiltration rate in a sandy loamy soil that has been subjected to 14 years of irrigation with sodic waters. Nevertheless, more research is needed to quantify the amount of organic matter required, in conjunction with inorganic amendments, to economically reclaim sodic soils. A review of the major lessons and observations acquired in the remediation of oil and brine spills in Oklahoma prairie are addressed by Sublette et al. (2007).

The most common method for determining soil salinity and/or sodicity in the laboratory consists of taking soil extracts and measuring parameters such as soluble and exchangeable ions, pH,  $EC_e$ , and SAR (Muhammad, 1996). From a practical standpoint, this method is time consuming and requires special equipment. To overcome this difficulty, researchers have used various soil to water ratios for obtaining extracts (Magistad et al., 1945; Chang, 1953). The variation in the soil to water ratio used

by investigators have led to erroneous and misleading results. Afzal and Yasine (2002), demonstrated that an increase in the moisture content of a soil sample (corresponding soil:water ratios of 1:1, 1:2, 1:5, and 1:10) was accompanied by an increase in the pH of the extract and the concentration of soluble ions ( $\text{Na}$ ,  $\text{Ca} + \text{Mg}$ ,  $\text{CO}_3 + \text{HCO}_3$ ,  $\text{SO}_4$ ) and a decrease in  $\text{ExNa} + \text{K}$ ,  $\text{ExCa} + \text{Mg}$ , and ESP. The authors (Afzal and Yasine, 2002) suggest the use of the saturated paste method for an accurate determination of pH, soluble salts, and exchangeable cations and thus for classification and reclamation of salt-affected soils (Afzal and Yasine, 2002).

## 4.7 CONCLUSIONS

The DI could predict RSHC. The relationship between RSHC and DI is not universal; however, it is unique to a particular soil under a given set of leaching conditions. The properties that appear to influence the RSHC–DI relationship of soils in humid regions are soil mineralogy, soil texture, soil pH, ionic strength, and solution composition. Information on humid region soils clearly demonstrates the following points: (a) The RSHC is related to clay DI, (b) the relationship between RSHC and DI is dependent upon ionic strength and pH, and (c) soils exhibit different RSCH–DI relationships. Furthermore, soils of the humid regions appear to behave differently with respect to  $\text{Na}^+ - \text{Ca}^{2+}$  exchange and physical stability in relationship to soils of arid regions.

## 5.1 INTRODUCTION

The production of reactive oxygen species (ROS) is an unavoidable consequence of aerobic metabolism. ROS are highly reactive products that are generated due to the stepwise reduction of molecular oxygen ( $O_2$ ) by high-energy exposure or as a result of electron-transfer chemical reactions. ROS include free radicals as well as the nonradical molecules of high reactivity, such as superoxide anion ( $O_2^{\cdot-}$ ), hydroxyl radical ( $\cdot OH$ ), hydrogen peroxide ( $H_2O_2$ ), singlet oxygen ( $^1O_2$ ) etc. Dual roles for ROS in plants have been suggested, as they serve as key regulators of growth, development, and defense pathways, as well as at excessive levels they cause oxidative damage to biomolecules leading to toxicity in the cell (Mittler et al., 2004). Stressful conditions of the environment such as drought, salt stress, chilling, heat shock, excess levels of heavy metals, anaerobiosis, UV-B radiation, gaseous pollutants lead to the enhanced generation of ROS in plants due to the disruption of cellular homeostasis (Yan et al., 1996; Pellinen et al., 1999; Shah et al., 2001; Mittler, 2002; Pasqualini et al., 2002; Sharma and Dubey, 2005; Suzuki and Mittler, 2006; Esfandiari et al., 2008; Hu et al., 2008; Han et al., 2009; Kumutha et al., 2009; Maheshwari and Dubey, 2009; Sairam et al., 2009; Tanou et al., 2009). The enhanced production of ROS during abiotic stresses can pose a threat to cells by causing the peroxidation of lipids, oxidation of proteins, damage to nucleic acids, enzyme inhibition, activation of programmed cell death (PCD) pathway and ultimately cell death (Shah et al., 2001; Mittler, 2002; Pasqualini et al., 2003; Verma and Dubey, 2003; Meriga et al., 2004; Sharma and Dubey, 2005, 2007; Maheshwari and Dubey, 2009). ROS are viewed as the cellular indicators of stress as they serve as secondary messengers in the stress response signal transduction pathway. ROS also play an important role in lignification and other cross-linking processes in the cell wall (Bradley et al., 1992; Ogawa et al., 1997; Desikin et al., 2001; Mittler, 2002). Because of the multifunctional roles of ROS, it is necessary for the cells to control the level of ROS tightly to avoid any oxidative injury and not to eliminate them completely. Scavenging or detoxification of excess ROS is achieved by an efficient antioxidative system comprising of the nonenzymic as well as enzymic antioxidants (Noctor and Foyer, 1998). Ascorbate (AsA), glutathione (GSH), carotenoids, tocopherols, and phenolics serve as potent nonenzymic antioxidants within the cell. The enzymic antioxidants include superoxide dismutase (SOD), catalase (CAT), guaiacol peroxidase (GPX), enzymes of ascorbate–glutathione (AsA–GSH) cycle such as ascorbate peroxidase (APX), monodehydroascorbate reductase (MDHAR), dehydroascorbate reductase (DHAR), and glutathione reductase (GR) (Noctor and Foyer, 1998). However, the equilibrium between production and scavenging of ROS is perturbed under stressful conditions; therefore the modulation of antioxidant levels constitutes an important adaptive response to withstand adverse environmental conditions (Foyer et al., 1994; Noctor et al., 2002; Pitzschke and Hirt, 2006). Various workers have reported increased activities of many enzymes of the antioxidant defense system in plants to combat oxidative stress induced by drought (Rajamickam et al., 2005; Sharma and Dubey, 2005), soil salinity (Lin and Kao, 2000; Tsai et al., 2005; Tanou et al., 2009), high temperature (Rijstenbil et al., 1994; Almeselmani et al., 2006; Yin et al., 2008), chilling (Fryer et al., 1998; Bafeel and Ibrahim, 2008; Radyuk et al., 2009), metal toxicity (Shah et al., 2001; Verma and Dubey, 2003; Sharma and Dubey, 2007; Maheshwari and Dubey, 2009), anaerobiosis (Lin et al., 2008; Kumutha et al., 2009), gaseous pollutants (Ranieri et al., 1997; Scabbba et al., 2003), and UV-B radiation (Santos et al., 1999; Agarwal and Shaheen, 2007). The maintenance of a high antioxidant capacity to scavenge the toxic ROS has been linked to increased tolerance of plants to these abiotic stresses (Agarwal and Shaheen, 2007; Zaefyzadeh et al., 2009).

Potential to engineer plants that overexpress genes for antioxidants provides an opportunity to develop plants with enhanced tolerance to abiotic stress. With the advancements in molecular biology and the availability of advanced genetic tools, considerable progress has been made in improving stress-induced oxidative stress tolerance in crop plants by developing transgenic lines with altered levels of antioxidants (Allen et al., 1997; Lee et al., 2007; Ashraf et al., 2008; Prashanth et al., 2008). However, as the ROS detoxification system is very complex, changing one component

of the antioxidative defense system may or may not change the capacity of the pathway as a whole (Tseng et al., 2007; Lee et al., 2009). Further, the overexpression of the combinations of antioxidant enzymes in transgenic plants has been shown to have synergistic effects on stress tolerance. Therefore, increased emphasis is being given to produce transgenic plants overexpressing genes associated with more than one antioxidant in order to achieve tolerance to multiple environmental stresses.

The present review focuses on the abiotic stress-induced ROS production, oxidative damage caused by ROS, and the role of antioxidative defense systems in plants growing under a wide range of abiotic stresses. The progress made during the last few decades in improving abiotic stress tolerance in crop plants using genes responsible for the synthesis of antioxidants involving biotechnological approaches has also been discussed.

## 5.2 REACTIVE OXYGEN SPECIES AND INDUCTION OF OXIDATIVE STRESS

Like all aerobes, plants use  $O_2$  as terminal electron acceptor. At ambient temperature, one-step full reduction of  $O_2$  to  $H_2O$  could proceed very slowly due to the requirement of high activation energy. When oxygen is exposed to high-energy or electron-transfer chemical reactions, it gets converted to various highly reactive chemical forms collectively known as ROS. Although, it has been shown that some of the ROS may function as important signaling molecules that alter gene expression and modulate the activity of specific defense proteins, all ROS are extremely harmful to organisms at high concentrations. Figure 5.1 shows various ROS that are produced either due to stepwise reduction of  $O_2$  or as a result of energy absorption. In plants, ROS are continuously produced by the inevitable leakage of electrons on to molecular oxygen from the electron transport activities of chloroplast, mitochondria, and plasma membrane (Pinto et al., 2003), or as a byproduct of various metabolic pathways such as respiration and photosynthesis (Foyer and Harbinson, 1994; Apel and Hirt, 2004; Tsukamoto et al., 2005). These ROS include highly reactive species such as  $O_2^{\cdot-}$ ,  $\cdot OH$ ,  $H_2O_2$ ,  $^1O_2$  etc., which disrupt the homeostasis of the organism by oxidatively damaging membrane lipids, proteins, chlorophylls, and nucleic acids (Kanazawa et al., 2000; Cassells and Curry, 2001; Jiang and Zhang, 2001; Sharma and Dubey, 2005, 2007; Konieczny et al., 2008; Maheshwari and Dubey, 2009).

**FIGURE 5.1** Activation of  $O_2$  occurs by two different mechanisms. Stepwise monovalent reduction of  $O_2$  leads to formation of  $O_2^{\cdot-}$ ,  $H_2O_2$ , and  $\cdot OH$ , whereas energy transfer to  $O_2$  leads to the formation of  $^1O_2$ . At low concentrations, ROS may function as regulators of growth, development, and as important signaling molecules altering gene expression and modulating the activity of defense pathways. However, at high concentrations, ROS are extremely harmful and cause oxidative stress.

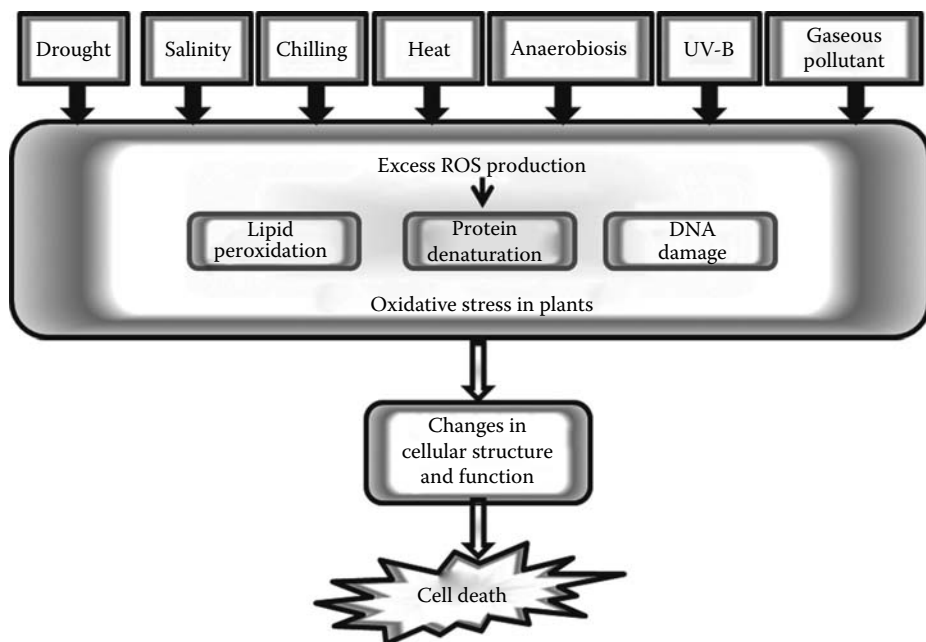

In its ground state, molecular  $O_2$  is relatively unreactive due to the presence of two unpaired electrons having parallel spin, which makes it paramagnetic (Apel and Hirt, 2004). Activation of  $O_2$  may occur by two different mechanisms: monovalent reduction or absorption of sufficient energy to reverse the spin on one of the unpaired electrons. The stepwise monovalent reduction of  $O_2$  leads to the formation of  $O_2^{\cdot-}$ ,  $H_2O_2$ ,  $\cdot OH$ , etc., whereas energy transfer to  $O_2$  leads to the formation of  $^1O_2$  (Figure 5.1). Singlet oxygen is a highly destructive ROS, which reacts with most of the biological molecules at near diffusion-controlled rates (Foyer and Harbinson, 1994). It is much more reactive toward organic molecules and can last for 4  $\mu s$  in water and 100  $\mu s$  in a nonpolar environment (Foyer and Harbinson, 1994).  $O_2^{\cdot-}$  is produced if one electron is added to ground state oxygen. Plasma membrane-bound nicotinamide adenine dinucleotide phosphate (NADPH)-oxidases use cytosolic NADPH to produce  $O_2^{\cdot-}$  under abiotic stress conditions.  $O_2^{\cdot-}$  is a moderately reactive, short-lived ROS with a half-life of approx. 2–4  $\mu s$ .  $O_2^{\cdot-}$  is a nucleophilic reactant with both oxidizing and reducing properties (Halliwell, 1977). With regard to the molecules of biological importance,  $O_2^{\cdot-}$  can oxidize sulfur compounds, O-diphenols, AsA (Mishra, 1974; Miller and MacDowell, 1975), cytochrome C (McCord et al., 1977), metal ions, and metal complexes (McCord and Day, 1978).  $H_2O_2$  is produced in the SOD-catalyzed disproportionation of  $O_2^{\cdot-}$ , or from the reduction of  $O_2^{\cdot-}$  by AsA, manganese ions, or ferredoxin (Hideg, 1997). The  $H_2O_2$  is one of the major and the most stable ROS that regulates basic acclimatization, defense, and developmental processes in plants (Slesak et al., 2007). It has been shown to act as a signal transduction molecule in several developmental processes. Nevertheless, at high concentrations, it causes oxidative stress marked by increased lipid peroxidation and the alteration of membrane permeability (Imlay, 2003). The main source of  $\cdot OH$  in biological systems is the decomposition of  $H_2O_2$  in the Haber–Weiss reaction. This reaction is enhanced by the presence of a transition metal, such as  $Fe^{2+}$  (Fenton reaction) (Hideg, 1997).  $\cdot OH$  is the most reactive among all ROS.  $\cdot OH$  can potentially react with all biological molecules, can initiate self-perpetuating lipid peroxidation, and, because cells have no enzymatic mechanism to eliminate this highly reactive ROS, its excess production would eventually lead to cell death (Pinto et al., 2003).  $\cdot OH$  interacts with all biological molecules and causes subsequent cellular damages such as lipid peroxidation, protein damage, and membrane destruction (Foyer et al., 1997). The well-known reactivity of  $H_2O_2$  is not due to its reactivity per se, but due to the formation of highly reactive  $\cdot OH$ , which is strong oxidizing agent, and is formed in the presence of metal reductants (Boo and Jung, 1999).

The production of ROS under normal growth conditions in cells is low (240  $\mu M s^{-1}$   $O_2^{\cdot-}$  and a steady state level of 0.5  $\mu M$   $H_2O_2$  in chloroplasts) (Polle, 2001). However, the various stressful conditions of the environment that disrupt the cellular homeostasis enhance the production of ROS (upto 720  $\mu M s^{-1}$   $O_2^{\cdot-}$  and a steady state level of 5–15  $\mu M$   $H_2O_2$ ) (Polle, 2001). When the level of ROS exceeds the defense mechanisms, a cell is said to be in a state of “oxidative stress.” Oxidative stress is defined as a shift of the balance between prooxidative and antioxidative reactions in favor of the former (Grzegorz, 1997). Figure 5.2 shows the enhanced production of ROS in plants growing under various abiotic stresses such as drought, salinity, extremes of temperature, excessive levels of metals, anaerobiosis, gaseous pollutants, and UV-B radiation. The enhanced level of these ROS causes oxidative damage to biomolecules such as membrane lipids, proteins, enzymes, nucleic acids, chloroplast pigments, etc. (Dat et al., 2000; Shah et al., 2001; Mittler, 2002; Pasqualini et al., 2003; Verma and Dubey, 2003; Meriga et al., 2004; Posmyk et al., 2005; Sharma and Dubey, 2005, 2007; Maheshwari and Dubey, 2009).

### 5.2.1 LIPID PEROXIDATION

Lipid peroxidation is a normal metabolic process associated with the developmental processes of plants, including the juvenile stage of growth, the production of odor volatiles, senescence, and the formation of compounds like jasmonic acid under normal aerobic conditions (Anderson, 1995). Both free radicals as well as enzymes can lead to the initiation of lipid peroxidation in

**FIGURE 5.2** Various abiotic stresses like drought, salinity, extreme temperatures, heavy metals, anaerobiosis, gaseous pollutants, and UV-B radiation cause enhanced production of ROS in plants. These ROS cause oxidative damage to lipids, proteins, and nucleic acids, which in turn leads to changes in cellular structure and function and ultimately cell death.

both cellular and organellar membranes. Increased peroxidation (degradation) of lipids has been reported in plants growing under various stressful conditions such as drought (Sharma and Dubey, 2005; Esfandiari et al., 2008), salinity (Tanou et al., 2009), chilling (O’Kane et al., 1996), heat (El-Shintinawy et al., 2004), metal toxicity (Shah et al., 2001; Verma and Dubey, 2003; Sharma and Dubey, 2007; Maheshwari and Dubey, 2009), anaerobiosis (Blokhina et al., 1999; Kumutha et al., 2009), UV-B exposure (Yannarelli et al., 2006), gaseous pollutants (Puckette et al., 2007), etc. Increase in lipid peroxidation under these stresses parallels with the increased production of ROS. Lipid peroxidation, in both cellular and organellar membranes, takes place when above-threshold ROS levels are reached, thereby not only directly affecting normal cellular functioning, but also aggravating the oxidative stress through production of lipid-derived radicals (Montillet et al., 2005). The level of lipid peroxidation has been widely used as an indicator of free radical mediated damage to cell membranes under stressful conditions. Malondialdehyde (MDA) is one of the final products of the peroxidation of unsaturated fatty acids in phospholipids and is responsible for cell membrane damage (Halliwell and Gutteridge, 1989). Yamauchi et al. (2008) showed that MDA generated in chloroplasts from peroxidized linolenic acid modifies proteins in heat-stressed plants. Using linolenic acid-deficient mutants (*fad3fad7fad8* triple mutant), it was concluded that linolenic acid could be a major source of protein modification by MDA in heat-stressed plants (Yamauchi et al., 2008).

The polyunsaturated fatty acids (PUFA) present in membrane phospholipids are particularly sensitive to attack by  $\cdot\text{OH}$  and other oxidants. When PUFA in biomembranes are peroxidized, a great diversity of aldehydes is formed, some of which are highly reactive. The peroxidation of PUFA by ROS attack can lead to chain breakage and thereby increase in membrane fluidity and permeability. Phospholipids are essential components of the membrane that surrounds the cell as well as other cellular structures, such as nucleus and mitochondria, and therefore damage to phospholipids can affect the viability of the cells (Woessmann et al., 1999). There are two common sites of oxygen free radical attack on the phospholipid molecules—the unsaturated (double) bond between two carbon atoms that can be easily obtained in chemical reaction and interaction with other substances and

the ester linkage between glycerol and the fatty acid. It has been suggested that decrease in cell membrane stability or increase in membrane permeability reflects the extent of lipid peroxidation caused by ROS (Sairam et al., 2002).

### 5.2.2 PROTEIN MODIFICATION

The attack of ROS on proteins results in the site-specific amino acid modification, fragmentation of the peptide chain, aggregation of cross-linked reaction products, altered electric charge, and increased susceptibility of proteins to proteolysis. ROS may cause the modification of proteins in a variety of ways, some are direct and others indirect. Direct modification involves modulation of a protein's activity through nitrosylation, carbonylation, disulfide bond formation, and glutathionylation. Proteins can be modified indirectly by conjugation with the breakdown products of fatty acid peroxidation (Yamauchi et al., 2008). As a consequence of excessive ROS production, tissues injured by oxidative stress generally contain the increased concentrations of carbonylated proteins (Dean et al., 1993). The enhanced modification of proteins has been reported in plants under various stresses (Rao et al., 1995; Sharma and Dubey, 2005, 2007; Maheshwari and Dubey, 2009; Tanou et al., 2009). The amino acids in a peptide differ in their susceptibility to attack by ROS and the various forms of ROS differ in their potential reactivity.  $\cdot\text{OH}$  and alkoxyl radicals are mainly involved in the oxidation of proteins. Sulfur-containing amino acids and thiol groups specifically are very susceptible sites for attack by ROS. Activated oxygen can abstract an H atom from cysteine residues to form a thiyl radical that will cross-link to a second thiyl radical to form a disulfide bridge. Several heavy metals including Cd, Pb, and Hg have been shown to cause the depletion of protein bound thiol groups (Stohs and Bagchi, 1995). Cytosolic proteins have a tendency to maintain their cysteine residues in reduced and native form, whereas many secreted proteins have evolved to be more stable when their cysteines are joined in disulfide bonds. Thus, changes in the reducing environment of the cytosol can have profound effects on protein folding and activity. It seems likely that unwanted disulfide bonds are generated in the normal resident proteins of the cytosol during oxidative stress (Cabiscol et al., 2000). Alternatively, oxygen can add to a methionine to form methionine sulfoxide derivative. A protein methionine sulfoxide reductase has been detected in pea chloroplasts (Ferguson and Burke, 1992). This enzyme reduces the methionyl sulfoxide back to methionyl residues in the presence of thioredoxin (Brot and Weissbach, 1982). Some forms of free radical attack on proteins are not reversible, for example, the oxidation of iron-sulfur centers by  $\text{O}_2^{\cdot-}$  destroys enzymatic function (Gardner and Fridovich, 1991). In these cases, the metal (Fe) binds to a divalent cation-binding site on the protein. The metal (Fe) then reacts in a Fenton reaction to form a  $\cdot\text{OH}$  that rapidly oxidizes an amino acid residue at or near the cation-binding site of the protein (Stadtman, 1986). Tyrosine is readily cross-linked to form bityrosine products (Davies, 1987; Malencik and Anderson, 2003). Histidine, lysine, proline, arginine, threonine, and serine form carbonyl groups on oxidation (Stadtman, 1986). With the finding that these amino acids are oxidized to carbonyl derivatives, several methods have been developed to detect the carbonyl content of proteins and used to measure protein damage (Cabiscol et al., 2000). The amino acids cysteine, methionine, and histidine are especially sensitive to attack and oxidation by  $\cdot\text{OH}$ . Accordingly, enzymes in which these amino acids are located at positions that are critical to enzyme activity will become inactivated by the interaction of ROS.

Oxidized proteins serve as better substrates for proteolytic digestion and proteolytic pathways could provide a valuable line of "secondary antioxidant defense" (Cabiscol et al., 2000). A strong correlation has been demonstrated between increased hydrophobicity on the protein surface and the recognition and proteolytic degradation of oxidatively modified proteins. Many intracellular proteins are degraded by the multicatalytic proteinase complexes, also called proteasomes, in a nonlysosomal pathway (Cabiscol et al., 2000). It has been suggested that protein oxidation could

predispose it to ubiquitination, which in turn would be a target for proteasomal degradation. It seems that after a certain degree of oxidative damage, further damage causes a decrease in proteolytic susceptibility. Several studies have revealed that heavily oxidized proteins, extensively cross-linked and aggregated, are not only poor substrates for degradation but also can inhibit proteases from degrading other oxidized proteins (Grune et al., 1997). The removal of damaged proteins is necessary to prevent their accumulation, which could compromise the correct metabolism of any cell exposed to oxidative stress.

Specific proteins appear to be particularly vulnerable to oxidative carbonylation in the matrix of plant mitochondria; these include several enzymes of the Krebs cycle, glycine decarboxylase, SOD, and heat shock proteins. Plant mitochondria contain a number of different proteases, but their role in removing oxidatively damaged proteins is, as yet, unclear (Moller and Kristensen, 2004). Among the techniques developed for the identification of oxidative stress-induced modifications of proteins, the so-called redox proteome, proteomics appears to be the best-suited approach. Oxidative stress leaves different footprints in the cell in the form of different oxidatively modified components and, using the redox proteome, it will be possible to decipher the potential roles played by ROS-induced modifications in stressed cells (Rinalducci et al., 2008).

### 5.2.3 DNA DAMAGE

DNA is cell's genetic material and any damage to the DNA can result in changes (i.e., mutation) in the encoded proteins, which may lead to malfunctions or the complete inactivation of the encoded proteins. Thus, it is essential for the viability of cell that the DNA remains intact. ROS are a major source of DNA damage (Imlay and Linn, 1986) and cause strand breaks, removal of nucleotides, and a variety of modifications in the organic bases of the nucleotides. Changes in the nucleotides of one strand can result in mismatches with the nucleotides in the other strand, yielding subsequent mutations. Although cells have developed repair mechanisms to correct naturally occurring changes in the DNA, additional or excessive changes caused by ROS or other agents can lead to permanent damage to the DNA with potentially detrimental effects for the cell (Chen et al., 2002). Mitochondrial and chloroplast DNA are more susceptible to oxidative damage than nuclear DNA due to the lack of protective protein, histones, and close locations to the ROS-producing systems in the former (Richter, 1992). Enhanced DNA degradation has been observed in plants exposed to various environmental stresses such as salinity (Liu et al., 2000), metal toxicity (Meriga et al., 2004), and gaseous pollutants (Pasqualini et al., 2003).

Both the sugar and base moieties are susceptible to oxidation by ROS. The degradation of bases produces numerous products, including 8-hydroxyguanine, hydroxymethyl urea, urea, thymine glycol, thymine, and adenine ring-opened and saturated products (Tsuboi et al., 1998). 8-Hydroxyguanine is the most commonly observed product. The principle cause of single-strand breaks is the oxidation of the sugar moiety by the  $\cdot\text{OH}$ . Under physiological conditions, neither  $\text{H}_2\text{O}_2$  alone nor  $\text{O}_2^{\cdot-}$  can cause *in vitro* strand breakage. Therefore, it was concluded that the toxicity associated with these ROS *in vivo* is most likely the result of Fenton reaction. Imlay and Linn (1986) concluded from their studies on *E. coli* mutants that a Fenton-active metal is probably chelated to phosphodiester linkage in DNA. When this metal is reduced by NADP(H) or  $\text{O}_2^{\cdot-}$ , it will react with  $\text{H}_2\text{O}_2$  to form the  $\cdot\text{OH}$  (Imlay and Linn, 1986).  $\cdot\text{OH}$  then oxidizes an adjacent sugar or base causing the breakage of the DNA chain. When  $\cdot\text{OH}$  attacks either DNA or proteins associated with it, DNA protein cross-links are formed (Oleinick et al., 1986). DNA protein cross-links cannot be readily repaired and may be lethal if replication or transcription precedes repair.

$\cdot\text{OH}$  reacts with free carbohydrates, such as sugars, and polyols (Smirnoff and Cumbe, 1989). The oxidation of sugars with  $\cdot\text{OH}$  often releases formic acid as the main breakdown product (Isbell et al., 1973). Plant cell wall polysaccharides have been shown to be susceptible to oxidative scission mediated by  $\cdot\text{OH}$  *in vitro* under physiologically relevant conditions (Fry, 1998).

### 5.3 ANTIOXIDATIVE DEFENSE SYSTEM IN PLANTS

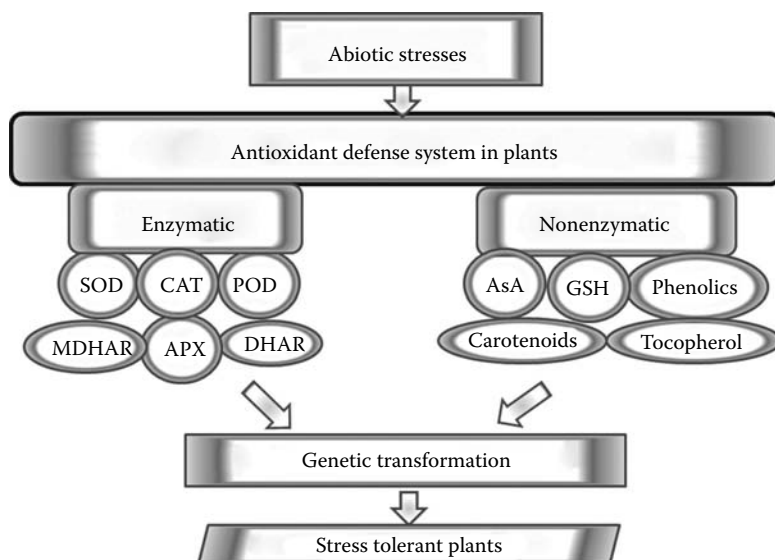

The balance between production and quenching of ROS may be perturbed by a number of adverse environmental factors, giving rise to rapid increases in intracellular ROS levels (Foyer et al., 1994; Noctor et al., 2002; Pitzschke and Hirt, 2006). The accumulation of ROS during abiotic stresses induces oxidative damage to lipids, proteins, and nucleic acids. Table 5.1 describes various plant species examined, in which different abiotic stresses cause overproduction of ROS leading to oxidative damage. In order to avoid the oxidative damage, higher plants possess a complex antioxidative defense system comprising of nonenzymatic and enzymatic components. A detailed account of these components has been presented in Figure 5.3. In plant cells, specific ROS-producing and scavenging systems are found in different organelles such as chloroplasts, mitochondria, and peroxisomes, and the ROS-scavenging pathways from different cellular compartments are coordinated (Pang and Wang, 2008).

#### 5.3.1 NONENZYMATIC DEFENSE SYSTEM

Nonenzymic components of the antioxidative defense system include the major cellular redox buffers AsA and GSH as well as tocopherol, carotenoids, and phenolic compounds. They interact with numerous cellular components and, in addition to crucial roles in defense and as enzyme cofactors, these antioxidants influence plant growth and development by modulating processes from mitosis and cell elongation to senescence and cell death (de Pinto and De Gara, 2004; Potters et al., 2004; Tokunaga et al., 2005). Mutants with decreased AsA, GSH, and tocopherol content have been shown to be hypersensitive to stress (Howden et al., 1995; Conklin et al., 1996; Huang et al., 2005; Semchuk et al., 2009).

**TABLE 5.1**  
**Abiotic Stresses Overproduce ROS and Cause Oxidative Damage to Different Plant Species**

| Abiotic Stress     | Plants                     | References                    |
|--------------------|----------------------------|-------------------------------|

**FIGURE 5.3** Antioxidant defense system comprises enzymatic and nonenzymatic components. These components, singly or in combination, can be successfully used as attractive targets to produce abiotic stress-tolerant plants using biotechnological approaches.

### 5.3.1.1 Ascorbate

Ascorbate is the most abundant low-molecular-weight antioxidant in plants and is proposed to function, along with other members of the antioxidant network, in controlling the level of ROS (Colville and Smirnoff, 2008). AsA has been shown to play an important role in several physiological processes in plants, including growth, differentiation, and metabolism. AsA has a key role in defense against oxidative stress and is particularly abundant in photosynthetic tissues (Smirnoff et al., 2004). It exists in the reduced state (AsA) as well as in oxidized forms (such as monodehydroascorbate; MDHA and dehydroascorbate; DHA) in plants. Most of AsA, almost more than 90%, is localized in cytoplasm, but unlike other soluble antioxidants, a substantial portion is exported to the apoplast, where it is present in millimolar concentration. Apoplastic AsA is believed to represent the first line of defense against potentially damaging external oxidants (Barnes et al., 2002). AsA protects critical macromolecules from oxidative damage.

AsA has a key role in the removal of  $\text{H}_2\text{O}_2$  via AsA–GSH cycle (Pinto et al., 2003). It also reacts directly with  $\text{O}_2^{\cdot-}$ ,  $\text{H}_2\text{O}_2$ , or the tocopheroxyl radical to form MDHA and DHA. The oxidation of AsA occurs in two sequential steps, first producing MDHA and subsequently DHA. The MDHA radical is also a primary product of APX reaction in the chloroplasts (Asada, 1997). The MDHA can either spontaneously dismutate or it gets reduced to AsA by NADP(H)-dependent enzyme, MDHAR (Miyake and Asada, 1994). If MDHA is not rapidly rereduced to AsA, the MDHA radical spontaneously disproportionates to AsA and DHA. DHA is also highly unstable at pH values greater than 6.0 and gets decomposed to tartarate and oxalate (Noctor and Foyer, 1998). To prevent this, DHA is rapidly reduced to AsA by the enzyme DHAR using reducing equivalents from GSH (Asada, 1996). AsA level has been reported to alter in response to drought (Sharma and Dubey, 2005; Esfandiari et al., 2008), salinity (Hernandez et al., 2001), chilling (Radyuk et al., 2009), metal toxicity (Sharma and Dubey, 2007; Maheshwari and Dubey, 2009), anaerobiosis (Lin et al., 2004), gaseous pollutants (Ranieri et al., 1997; Scebba et al., 2003; Severino et al., 2007), UV-B radiation (Agarwal and Shaheen, 2007), etc. The level of AsA under environmental stresses depends on the balance between the rates and the capacity of AsA biosynthesis and turnover related to antioxidant demand (Chaves et al., 2002). AsA concentration has a crucial role in the regulation of the compartmentalization of the

antioxidant system in *Arabidopsis*. In AsA deficient mutants of *Arabidopsis vtc-1*, total AsA in the apoplast decreased by nearly 23% of the wild-type value. Total leaf peroxidase activity increased in the mutants and compartment-specific differences in APX activity were observed. The activity and expression of cytosolic APX increased, whereas that for chloroplast APX, isoforms either remained unchanged or slightly decreased. Mutant studies have shown the importance of AsA in abiotic stress tolerance in plants. Low intrinsic AsA level in the *vtc-1* mutant under salt stress induced a dramatic decrease in the reduced form of AsA, which resulted in enhanced ROS contents in the *vtc-1* mutants (Huang et al., 2005). Similarly, AsA-deficient mutant *vtc-1* was found to be more sensitive to supplementary UV-B treatment than wild type plants (Gao and Zhang, 2008).

### 5.3.1.2 Glutathione

The reduced form of the tripeptide glutathione ( $\gamma$ -glutamyl-cysteinyl-glycine, GSH), is the major low-molecular-weight nonprotein thiol present in most plants. GSH is synthesized in the cytosol and chloroplasts of plant cells by compartment-specific isoforms of  $\gamma$ -glutamyl-cysteinyl synthetase ( $\gamma$ -ECS) and glutathione synthetase (GS). Besides serving as a key antioxidant within the cell, GSH acts as a redox buffer, is involved in the detoxification of xenobiotics, and it serves as a precursor for the synthesis of phytochelatins, which are crucial in controlling cellular heavy metal concentrations by chelating and sequestering them in vacuoles (Foyer et al., 2001). Due to its reducing power, GSH plays an important role in diverse biological processes in order to maintain cellular homeostasis, such as cell growth/division, metabolic reducing reactions, transmembrane transport, receptor actions, synthesis of proteins and nucleic acids, etc. (Foyer et al., 1997). GSH functions as an antioxidant in many ways. It can react chemically with  $O_2^{\cdot-}$ ,  $\cdot OH$ ,  $H_2O_2$  and, therefore, can function directly as a free radical scavenger. GSH can protect macromolecules (i.e., proteins, lipids, DNA) either by the formation of adducts directly with reactive electrophiles (glutathiolation) or by acting as proton donor in the presence of ROS or organic free radicals yielding glutathione disulfide (GSSG) (Asada, 1994). Under unstressed conditions, GSSG is reduced efficiently back to GSH by the action of enzyme GR present in cytosol, mitochondria, and chloroplasts. In extreme stress situations, the rate of GSH oxidation exceeds GSH reduction and the ratio of GSH/GSSG decreases (Foyer et al., 2001). GSH recycles AsA from its oxidized form to its reduced form by the enzyme DHAR (Loewus, 1988). GSH can also reduce DHA by a nonenzymic mechanism at pH > 7 and at GSH concentrations greater than 1 mM. This may be a significant pathway in chloroplasts, where in the presence of light, pH remains around 8 and GSH concentration may be as high as 5 mM (Foyer and Halliwell, 1976). The enzyme GR uses NADPH as a cofactor to reduce GSSG back to two molecules of GSH. The reductant GSH, together with its oxidized sulfur-sulfur linked form (GSSG), forms a very potent redox couple and is considered to be the major redox buffer of the cell. Oxidative stress results in the formation of GSSG at the expense of GSH. This shift in the ratio of GSH/GSSG would change the redox status to a less negative potential. If this potential rises too much, it would either stimulate or impede redox-sensitive important cellular processes like signal transduction pathways, calcium release, enzyme activation, etc. (Watanabe et al., 1972; Ernest and Kim, 1973). Therefore, the generation and maintenance of reduced GSH pool, either by de novo synthesis or via recycling by GR, using NADPH as a cofactor and electron donor, is of vital importance for the cell. The role of GSH in the antioxidative defense system provides a rationale for its use as a stress marker. A time-course analysis to monitor the level of GSH during stress response indicated that an initial stress response was related to changes in the GSH redox state, whereas acclimation was marked by increased GSH concentrations, increased GSH synthesizing enzyme activities, and/or a more reduced redox state of GSH (Tausz et al., 2004). The latter was interpreted as overcompensation, leading to the enhanced regeneration of GSH. Deteriorative effects on strong stress impacts were related to the progressive degradation and oxidation of the GSH pool. When apple trees were subjected to progressive drought, the initial response was a little oxidation of the GSH pool, followed by increased GSH concentrations. When the stress increased, GSH concentrations dropped and redox state became more oxidized, which marked the degradation of the system (Tausz et al., 2004). Similar to drought stress, the altered ratio of GSH/GSSG has been observed in plants under various stresses

like salinity (Hefny and Abdel-Kader, 2009), chilling (Radyuk et al., 2009), metal toxicity (Sharma and Dubey, 2007; Maheshwari and Dubey, 2009), anaerobiosis (Lin et al., 2004), and gaseous pollutants (Scebba et al., 2003). However, the importance of the GSH system relative to the other components of the antioxidative defense system, as well as relative to stress avoidance strategies, remains to be established (Tausz et al., 2004).

### 5.3.1.3 Tocopherol and Carotenoids

Like AsA and GSH, carotenoids and tocopherol are important antioxidants of the plant cell. Tocopherols ( $\alpha$ ,  $\beta$ ,  $\gamma$ , and  $\delta$ ) represent a group of lipophilic antioxidants that are synthesized only by photosynthetic organisms. They scavenge oxygen free radicals, lipid peroxy radicals, and  $^1\text{O}_2$  (Diplock et al., 1989). Fully substituted benzoquinone ring and fully reduced phytyl chain of tocopherol act as antioxidants in redox interactions with  $^1\text{O}_2$  (Fryer, 1992; Halliwell and Gutteridge, 1999). Tocopherol also acts as a membrane stabilizer. It is widely believed that the protection of pigments and proteins of photosynthetic system and PUFA from oxidative damage caused by ROS is the main function of tocopherols. Mutants of *Arabidopsis thaliana* with T-DNA insertions in tocopherol biosynthesis genes, tocopherol cyclase (*vte1*), and  $\gamma$ -tocopherol methyltransferase (*vte4*) showed higher concentration of protein carbonyl groups and GSSG compared to the wild type, indicating the development of oxidative stress (Semchuk et al., 2009). The accumulation of  $\alpha$ -tocopherol has been shown to induce tolerance to chilling, water deficit and, salinity in different plant species (Yamaguchi-Shinozaki and Shinozaki, 1994; Munné-Bosch et al., 1999; Guo et al., 2006; Bafeel and Ibrahim, 2008).

Carotenoids function as accessory pigments in light harvesting during photosynthesis, but, perhaps, a more important role of carotenoids is their ability to detoxify the various forms of activated oxygen species (Young, 1991). Carotenoids also serve as precursors to signaling molecules that influence plant development and biotic/abiotic stress responses (Li et al., 2008). The ability of carotenoids to scavenge, prevent, or minimize the production of triplet chlorophyll may be accounted for by their chemical specificity. Carotenoids contain a chain of isoprenic residues bearing numerous conjugated double bonds, which allows easy energy uptake from excited molecules and dissipation of excess energy as heat (Edge et al., 1997; Mittler, 2002). Yildiz-Aktas et al. (2009) observed a higher content of carotenoids and antiradical capacity and lower MDA level in the drought-tolerant genotype of cotton compared with the sensitive genotype at normal water supply. In plants subjected to water deficit, a decline in the level of carotenoids and antiradical capacity was observed. However, this response was less pronounced in the tolerant than in the sensitive genotype; that is, despite the stress conditions imposed, the tolerant plants maintained a more effective defense system. Hence, carotenoids were correlated with drought tolerance in cotton plants (Yildiz-Aktas et al., 2009). The first committed step in the plastid-localized biosynthetic pathway of carotenoids is mediated by the nuclear-encoded phytoene synthase (PSY). PSY1 was found to have a role in heat stress tolerance (Li et al., 2008). Chromoplast carotenoids are known to accumulate in green tissues experiencing stress conditions, and studies indicate that they provide efficient protection against oxidative stress. Experiments conducted to test the role of ROS as the regulators of chromoplast carotenoid biosynthesis *in vivo*, revealed that the addition of ROS progenitors, such as menadione, *tert*-butylhydroperoxide, or paraquat and prooxidants like diamide or buthionine sulfoximine to green pericarp discs of pepper fruits, rapidly and dramatically induced the simultaneous expression of multiple carotenogenic gene-related mRNAs that could give rise to capsanthin. Similarly, down-regulation of CAT by amitrole induces the expression of carotenogenic gene-related mRNAs, leading to the synthesis of capsanthin in excised green pericarp discs. ROS signals from plastids and mitochondria were also shown to contribute significantly to this process (Bouvier et al., 1998).

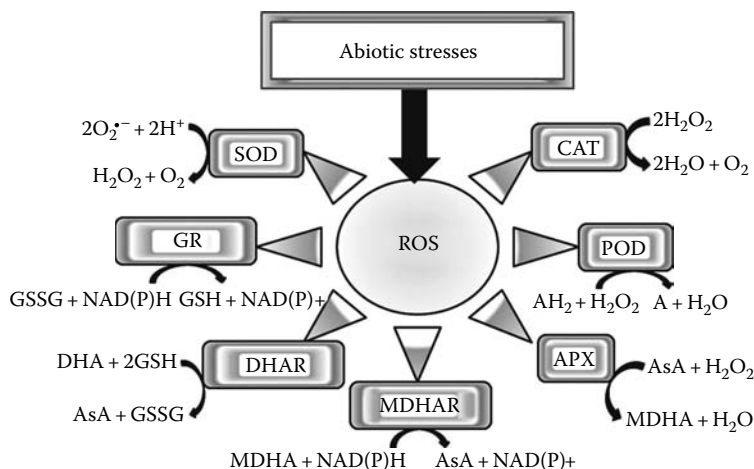

### 5.3.1.4 Phenolic Compounds

Besides the well-studied nonenzymic antioxidants like AsA, GSH, tocopherols, recent works have begun to highlight the potential role of flavonoids, phenylpropanoids, and phenolic acids as effective

antioxidants. Phenolics contain an aromatic ring with —OH or OCH<sub>3</sub> substituents that together contribute to their biological activity. There are two major phenolic classes, hydroxycinnamic acids and flavonoids. Flavonoids act as antioxidants and UV-B protectant. Most flavonoids outperform well-known antioxidants, AsA, and  $\alpha$ -tocopherol, in *in vitro* antioxidant assays because of their strong capacity to donate electrons or hydrogen atoms. However, the antioxidant function of flavonoids in plants is still a matter of debate (Hernandez et al., 2009). During heavy metal stress, phenolic compounds can act as metal chelators and on the other hand, phenolics can directly scavenge molecular species of active oxygen. Phenolics, especially flavonoids and phenylpropanoids, are oxidized by peroxidase, and act in H<sub>2</sub>O<sub>2</sub>-scavenging, phenolic/AsA/POD system. Their antioxidant action resides mainly in their chemical structure. There is some evidence of the induction of phenolic metabolism in plants as a response to multiple stresses (including heavy metal stress) (Michalak, 2006). When the influence of a high copper sulfate concentration on lipid peroxidation and the contents of total phenolic compounds in roots of lentil (*Lens culinaris* Medic.) cvs. Krak and Tina were investigated, it was observed that ROS could serve as a common signal for acclimation to Cu<sup>2+</sup> stress and could cause the accumulation of total phenolic compounds in dark-grown roots (Janas et al., 2009). It is believed that phenolics including various flavonoids serve as “sunscreens” to UV exposure: in particular, flavonoids play pivotal roles in absorbing free radicals, quenching <sup>1</sup>O<sub>2</sub>, and decomposing peroxides. A mutant *Arabidopsis thaliana* L., which displays a dramatic increase in sensitivity to UV-B radiation compared with wild-type plants, was found to have a single gene defect that led to a block in the synthesis of a group of flavonoids that normally accumulate in developing wild-type *Arabidopsis* and that increase in concentration when plants are exposed to UV radiation. One of these compounds has been identified as a rhamnosylated derivative of the flavonol, kaempferol. Therefore, it was suggested that flavonoids play an important role in the protection of plants from the damaging effects of UV-B light (Lois and Buchanan, 1994).

### 5.3.2 ENZYMATIC DEFENSE SYSTEM

The enzymatic components of the antioxidative defense system comprise several antioxidant enzymes such as SOD, CAT, GPX, enzymes of AsA–GSH cycle APX, MDHAR, DHAR, and GR (Noctor and Foyer, 1998). These enzymes operate in different subcellular compartments and respond in concert when cells are exposed to oxidative stress. A detailed account of the reactions catalyzed by various antioxidant enzymes has been presented in Figure 5.4.

**FIGURE 5.4** Reactions catalyzed by enzymes involved in antioxidative defense system in plants. The efficient scavenging/destruction of ROS generated during abiotic stresses requires the concerted action of these antioxidant enzymes.

### 5.3.2.1 Superoxide Dismutase

The enzyme SOD belongs to the group of metalloenzymes and catalyzes the disproportionation of  $O_2^{\cdot-}$  to  $O_2$  and  $H_2O_2$ . Within the cell, SOD constitutes the first line of defense against ROS (Alscher et al., 2002). This enzyme neutralizes the very reactive  $O_2^{\cdot-}$  produced in the different compartments of plant cells into  $O_2$  and  $H_2O_2$  with the rate  $10^4$  times faster than the spontaneous dismutation reaction (Fridovich, 1975). Since SOD is present in all aerobic organisms and in most of the sub-cellular compartments that generate activated oxygen, it has been assumed that SOD has a central role in defense against oxidative stress (Scandalios, 1993). While all compartments of the cell are possible sites for  $O_2^{\cdot-}$  formation, chloroplasts, mitochondria, and peroxisomes are thought to be the most important generators of ROS (Alscher et al., 2002). In plant systems, three isozymes of SOD, namely, Cu/Zn-SOD, Mn-SOD, Fe-SOD have been reported (Fridovich, 1989; Racchi et al., 2001). All forms of SOD are nuclear encoded and targeted to their respective subcellular compartments by an amino terminal targeting sequence (Bowler et al., 1992). Cu/Zn-SOD is predominantly found in cytosol, chloroplast, and mitochondria, Mn-SOD in mitochondria and peroxisomes, whereas Fe-SOD is predominantly present in chloroplasts (del Rio et al., 1998; Arora et al., 2002). Cu/Zn-SOD is cyanide sensitive whereas the other two (Mn-SOD and Fe-SOD) are cyanide insensitive (del Rio et al., 1998). Eukaryotic Cu/Zn-SOD isoforms are dimers whereas Mn-SOD isoforms of mitochondria are tetramers (Scandalios, 1993).

The activity of SOD has been reported to increase under diverse stress situations such as drought, salinity, heat, chilling, metal toxicity, anaerobiosis, exposure to ozone, UV-B, etc. (Bowler et al., 1992; Rao et al., 1996; Lee and Lee, 2000; Verma and Dubey, 2003; Sharma and Dubey, 2005, 2007; Almeselmani et al., 2006; Yin et al., 2008; Han et al., 2009; Hefny and Abdel-Kader, 2009; Kumutha et al., 2009; Maheshwari and Dubey, 2009), and the increased activity is often correlated with the tolerance of the plant against these stresses. Decreased level of SOD was observed in drought-sensitive durum wheat landraces, whereas in resistant and moderately resistant durum wheat landraces, SOD remained unchanged or increased. Therefore, it was suggested that SOD can be used as an indirect selection criterion for screening drought-resistant plant materials (Zaefyzadeh et al., 2009). The overproduction of SOD has been reported to result in enhanced oxidative stress tolerance in many plant species (McKersie et al., 1993; Perl et al., 1993; Foyer et al., 1994; Slooten et al., 1995a). Chary et al. (1994) constructed and characterized *Neurospora crassa* mutants that were null for *sod-1*, the gene that encodes Cu/Zn-SOD. Mutant strains were sensitive to elevated oxygen concentrations, and they exhibited an increased spontaneous mutation rate. The role of Mn-SOD in providing protection against ROS has been studied using Mn-SOD gene disruption. The nuclear gene for Mn-SOD of yeast mitochondria was inactivated by gene disruption. In the absence of oxygen, the mutant grew as rapidly as the wild-type parent. However, increasing concentrations of oxygen led to a progressive inhibition of growth. The properties of this mutant provide direct evidence that Mn-SOD contributes to the natural protection of cells against oxygen toxicity (van Loon et al., 1986). Similar to Cu/Zn-SOD and Mn-SOD, Fe-SOD has also been shown to play an important role in oxidative stress tolerance in plants. The transgenic *A. thaliana* line with high Fe-SOD activities showed enhanced tolerance to oxidative stress and showed increased growth rates compared to wild-type plants (Van Breusegem et al., 1999).

### 5.3.2.2 Catalase

Catalase is a tetrameric, heme-containing enzyme found in all aerobic organisms and catalyzes the dismutation of  $H_2O_2$  into water and oxygen.  $H_2O_2$  has been implicated in many stress conditions. In plants, CAT scavenges  $H_2O_2$  generated during mitochondrial electron transport,  $\beta$ -oxidation of fatty acids, and, most importantly, during photorespiratory oxidation (Scandalios et al., 1997). CAT is unique among  $H_2O_2$  degrading enzymes as it degrades  $H_2O_2$  without consuming cellular reducing equivalents. Therefore, when cells are stressed for energy and are rapidly generating  $H_2O_2$  through catabolic processes,  $H_2O_2$  is degraded by CAT in an energy efficient manner (Mallick and Mohn, 2000).

Different classes of CAT have been identified based on their expression profile. A nomenclature has been adopted for this classification (Willekens et al., 1994). Class I CATs are expressed in photosynthetic tissues and are regulated by light. Class II CATs are expressed at high levels in vascular tissues, whereas class III CATs are highly abundant in seeds and young seedlings (Willekens et al., 1994). CATs are very sensitive to light and have very rapid turnover rate similar to that of D1 protein of PS II (Hertwig et al., 1992). This may be as a result of light absorption by the heme group or perhaps inactivation due to  $\text{H}_2\text{O}_2$ . Abiotic stresses cause either the enhancement or depletion of CAT activity (Feierabend et al., 1992; Fu and Huang, 2001; El-Shintinawy et al., 2004; Sharma and Dubey, 2005; Moussa and Abdel-Aziz, 2008; Han et al., 2009; Kumutha et al., 2009; Noreen and Ashraf, 2009). The properties of CATs suggest that the enzyme is inefficient in removing low concentration of  $\text{H}_2\text{O}_2$  (Arora et al., 2002).

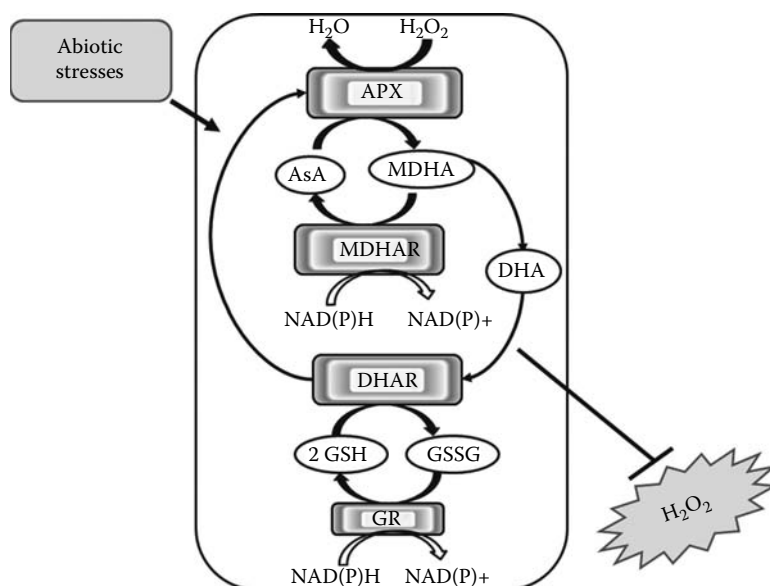

CATs function as a cellular sink for the removal of  $\text{H}_2\text{O}_2$ , as evidenced by the complementation of CAT deficiency by the exogenous application of CAT, and comparison of CAT-deficient and control leaf discs in removing external  $\text{H}_2\text{O}_2$ . Stress analysis revealed increased susceptibility of CAT-deficient plants to paraquat, salt, and ozone, but not to chilling (Willekens et al., 1997). Transgenic tobacco plants having 10% wild-type CAT activity showed no visible disorders at low light, but in elevated light, rapidly developed white necrotic lesions on the leaves. Leaf necrosis in such plants was correlated with the accumulation of GSSG and a fourfold decrease in AsA, indicating that CAT is critical for maintaining the redox balance during oxidative stress (Willekens et al., 1997). Palatnik et al. (2002), while investigating the antioxidant status in a CAT-deficient mutant of barley RPr79/4, and in its motherline cv. Maris Mink, observed that seedlings of the CAT-deficient mutant grown in a growth chamber under a 14-h photoperiod ( $200 \mu\text{mol quanta m}^{-2} \text{s}^{-1}$ ), showed higher concentrations of GSH and APX as compared to wild-type plants. An additional mitochondrial Mn-SOD isoenzyme was also detected in RPr79/4. When seedlings of the CAT-deficient mutant were grown at higher light intensities ( $370 \mu\text{mol quanta m}^{-2} \text{s}^{-1}$ ), a Cu/ZnSOD isoform and the cytosolic glutamine synthetase isoenzyme were concomitantly induced. Taken together, these results suggest that several defense mechanisms operating in different subcellular compartments respond in concert to compensate for CAT deficiency in barley seedlings exposed to oxidative stress (Palatnik et al., 2002).

### 5.3.2.3 Guaiacol Peroxidase

Peroxidases (PODs) belong to a large family of enzymes that occur ubiquitously in fungi, plants, and vertebrates and convert  $\text{H}_2\text{O}_2$  into  $\text{H}_2\text{O}$  and  $\text{O}_2$  (Mika and Luthje, 2003). Classical secretory plant PODs that commonly use guaiacol as a reducing substrate are also referred to as guaiacol peroxidase (GPX). These proteins usually contain a ferri protoporphyrin IX prosthetic group that oxidizes several substrates in the presence of  $\text{H}_2\text{O}_2$  (Vianello et al., 1997). Most secretory plant PODs are glycosylated (Johansson et al., 1992). These enzymes have four conserved disulfide bridges and contain two structural  $\text{Ca}^{2+}$  ions (Schuller et al., 1996). Many isoenzymes of GPX exist in plant tissues localized in vacuoles, the cell wall, and the cytosol (Asada, 1992). GPX oxidizes a wide range of organic substrates, and the oxidation processes are associated with many important biosynthetic processes. GPXs have been proposed to participate in the lignification of cell wall, degradation of IAA, biosynthesis of ethylene, wound healing, and defense against pathogens (Kobayashi et al., 1996). Both intracellular and extracellular PODs have an important role in the antioxidative response of plant cells (Siegel and Siegel, 1986). PODs can function as effective quenchers of reactive intermediary forms of  $\text{O}_2$  and peroxy radicals under stressed conditions (Vangronsveld and Clijsters, 1994). Various stressful conditions of the environment have been shown to induce the activity of PODs (Rao et al., 1996; Radotic et al., 2000; Shah et al., 2001; El-baky et al., 2003; Harinasut et al., 2003; Verma and Dubey, 2003; Sharma and Dubey, 2005, 2007; Moussa and Abdel-Aziz, 2008; Han et al., 2009; Maheshwari and Dubey, 2009). PODs have been used as biochemical markers for various types of abiotic and biotic stresses (Castillo et al., 1992). Radotic et al. (2000) correlated the increased activity of PODs to oxidative reactions under metal toxicity conditions and suggested its potential as a biomarker for sublethal metal toxicity in plants.

### 5.3.2.4 Enzymes of Ascorbate–Glutathione Cycle

Efficient scavenging/destruction of ROS generated during abiotic stresses require the action of several antioxidant enzymes. The AsA–GSH cycle, also referred to as Halliwell–Asada pathway, present in at least four different subcellular locations including the cytosol, chloroplast, mitochondria, and peroxisomes, scavenges  $\text{H}_2\text{O}_2$ . The AsA–GSH cycle involves successive oxidation and reduction of AsA, GSH, and NADPH catalyzed by the enzymes APX, MDHAR, DHAR, and GR (Figure 5.5). APX uses two molecules of AsA to reduce  $\text{H}_2\text{O}_2$  to water with a concomitant generation of two molecules of MDHA. APX is a member of Class I super family of heme PODs (Welinder, 1992). In higher plants, five chemically and enzymatically distinct isoenzymes of APX have been found differing in their subcellular localization and amino acid sequences. These are cytosolic, stromal, thylakoidal, mitochondrial, and the peroxisomal isoforms (Jimenez et al., 1997). The classification is based on sequence comparisons rather than on function. APX isoenzymes also differ in their molecular weight, substrate specificity, pH optima, and stability (Wang et al., 1999). Cytosolic APX has been characterized in photosynthetic as well as nonphotosynthetic tissues (Madhusudhan et al., 2003). The chloroplastic and cytosolic APX isoforms are specific for AsA as electron donor and the cytosolic isoenzymes are less sensitive to depletion of AsA than the chloroplastic isoenzymes including stromal- and thylakoid-bound enzymes (Ishikawa et al., 1998). Many workers have reported enhanced expression of APX in response to abiotic stresses such as drought, salinity, heat, chilling, metal toxicity, anaerobiosis, UV irradiation, gaseous pollutants, etc. (Rao et al., 1996; Boo and Jung, 1999; Sharma and Dubey, 2005, 2007; Han et al., 2009; Hefny and Abdel-Kader, 2009; Kumutha et al., 2009; Locato et al., 2009; Maheshwari and Dubey, 2009; Radyuk et al., 2009). The importance of APX in stress defense was demonstrated in APX-antisense transgenic tobacco that was highly susceptible to ozone injury compared to the wild-type plants (Orvar and Ellis, 1997). The overexpression of a cytosolic APX gene derived from pea (*Pisum sativum* L.) in transgenic tomato plants (*Lycopersicon esculentum* L.) resulted in lower electrolyte leakage (20%–23%) than wild type (44%) after exposure to 4°C. The visual assessment of transgenic

**FIGURE 5.5** Components of ascorbate–glutathione cycle play an important role in the decomposition of  $\text{H}_2\text{O}_2$  in plants under abiotic stresses. APX reduces  $\text{H}_2\text{O}_2$  to  $\text{H}_2\text{O}$  using AsA, which generates MDHA. MDHA can be reduced to AsA by MDHAR. If not reduced rapidly, MDHA is disproportionated into AsA and DHA. DHA is reduced to AsA by DHAR using GSH as the reducing agent. GSH gets converted to GSSG that, in turn, is reduced by GR using NADPH.

and wild-type lines exposed to salinity stress (200 or 250 mM) confirmed that the overexpression of APX minimized leaf damage. Moreover, APX activity was nearly 25- and 10-fold higher in the leaves of transgenic plants in response to chilling and salt stresses, respectively. Results substantiate that increased levels of APX activity brought about by the overexpression of a cytosolic APX gene may play an important role in ameliorating oxidative injury induced by chilling and salt stress (Wang et al., 2005b).

In plant cells, AsA is a major antioxidant that is part of the AsA–GSH cycle. MDHAR, the enzymatic component of this cycle, is involved in the regeneration of reduced AsA. MDHA radical produced in APX catalyzed reaction has a short lifetime and if not rapidly reduced, it disproportionates to AsA and DHA (Ushimaru et al., 1997). Within the cell, such as at the plasmalemma or at the thylakoid membrane, MDHA can be reduced directly to AsA. The electron donor for MDHA reduction may be b-type cytochrome, reduced ferredoxin, or NAD(P)H. The reaction is catalyzed by the enzyme MDHAR, which is found in several cellular compartments (Miyake and Asada, 1994). The isoenzymes of MDHAR have been reported to be present both inside and outside the plastids (De Leonardis et al., 1995) and in shoots, roots, dry seeds, as well as fruits (Ushimaru et al., 1997; Leterrier et al., 2005). Various research groups have shown increased activity of MDHAR in plants subjected to abiotic stresses (Boo and Jung, 1999; Sharma and Dubey, 2005, 2007; Locato et al., 2009; Maheshwari and Dubey, 2009). The presence of different regulatory motifs in the promoter region of the *MDAR1* gene has been suggested to be responsible for the distinct responses of plants to various stress conditions. The functional analysis of MDHAR isoforms present in the different cell compartments in pea plants grown under eight stress conditions, including continuous light, high light intensity, continuous dark, mechanical wounding, low and high temperatures, excess Cd, and under the application of the herbicide 2,4-dichlorophenoxyacetic acid revealed a significant induction of MDAR activity by high light intensity and Cd. On the other hand, expression studies demonstrated differential expression patterns of peroxisomal *MDAR 1* transcript in pea plants grown under these stressful conditions. These findings show that the peroxisomal *MDAR 1* has a differential regulation that could be indicative of its specific function in peroxisomes (Leterrier et al., 2005).

Despite the possibility of enzymic and nonenzymic regeneration of AsA directly from MDHA, some DHA is always produced when AsA is oxidized in leaves and other tissues. DHA is reduced to AsA by the action of DHAR using GSH as the reducing substrate (Ushimaru et al., 1997). DHAR is a key component of the AsA recycling system. DHAR is a monomeric thiol enzyme abundantly found in dry seeds, roots, and etiolated as well as green shoots. Three functional DHAR genes have been reported to be encoded in the *Arabidopsis* genome. Abiotic stresses such as drought, metal toxicity, chilling, ozone exposure etc., increase the activity of the DHAR in plants (Boo and Jung, 1999; Hernandez et al., 2001; Sharma and Dubey, 2005, 2007; Yoshida et al., 2006; Locato et al., 2009; Maheshwari and Dubey, 2009). An *Arabidopsis* mutant completely lacking cytosolic DHAR activity was found to be highly ozone sensitive. The amounts of total AsA and GSH were similar in both lines, but the amount of apoplastic AsA in the mutant was 61.5% lower. These results indicate that the apoplastic AsA, which is generated through the reduction of DHA by cytosolic DHAR, is important for ozone tolerance (Yoshida et al., 2006). Consistent upregulation of the gene encoding cytosolic DHAR was found in *L. japonicas*, which was found to be more tolerant to salt stress than other legumes. This upregulation of DHAR was correlated to its role in AsA recycling in the apoplast (Rubio et al., 2009).

Reaction catalyzed by DHAR generates GSSG that in turn gets rereduced to GSH using NADPH in a reaction catalyzed by enzyme GR. GR is a NAD(P)H-dependent enzyme ubiquitously present in mesophyll cells. Although it is located in chloroplasts, cytosol, and mitochondria, around 80% of GR activity in photosynthetic tissues is accounted for by chloroplastic isoforms (Edwards et al., 1990). GR has been purified and well characterized from the leaves of several plant species such as spinach (Halliwell and Foyer, 1978), pea (Kalt-Torres et al., 1984), and corn (Mahan and Burke, 1987). In most of the plants, GRs are homodimers with a molecular mass ranging from 100 to 150 kDa, containing one FAD per monomer. GR belongs to a group of flavoenzymes including lipoyl

dehydrogenase, thioredoxin reductase, tripanetine reductase, and mercuric reductase, and contain an essential disulfide group (Ghisla and Massey, 1989). The catalytic mechanism involves two steps: first, the flavin moiety is reduced by NADPH, the flavin is oxidized and a redox-active disulfide bridge is reduced to produce a thiolate anion and a cysteine. The second step involves the reduction of GSSG *via* thiol–disulfide interchange reactions (Ghisla and Massey, 1989). If the reduced enzyme is not reoxidized by GSSG, it can suffer a reversible inactivation. Several authors have reported the increased activity of this enzyme under abiotic stresses (Rao et al., 1996; Hernandez et al., 2001; Sharma and Dubey, 2005, 2007; Yoshida et al., 2006; Kumutha et al., 2009; Locato et al., 2009; Maheshwari and Dubey, 2009). Pastori and Trippi (1992) observed a correlation between the oxidative stress resistance and the activity of GR and suggested that oxidative stress caused by paraquat or  $\text{H}_2\text{O}_2$  could stimulate GR *de novo* synthesis, probably at the level of translation by pre-existing mRNA.

## 5.4 LEVEL OF ROS, EXTENT OF OXIDATIVE STRESS, AND THE STATUS OF ANTIOXIDATIVE DEFENSE SYSTEM UNDER VARIOUS ABIOTIC STRESSES

Oxidative stress is one of the major limiting factors in crop productivity. Various stressful conditions of the environment such as drought, salinity, extreme temperatures, excessive levels of metals in the soil, anaerobiosis, gaseous pollutants, UV-B radiation, etc., affect the physiological processes of plants and lead to the production of ROS that in turn cause oxidative damage at the cellular level (Radotic et al., 2000; Abarca et al., 2001). Active oxygen species must be rapidly processed if oxidative damage is to be averted. An efficient antioxidative defense system can scavenge overproduced ROS in plants. The lifetime of ROS within the cellular environment is determined by the efficiency of the antioxidative system (both nonenzymatic and enzymatic antioxidants), which provides crucial protection against oxidative damage (Noctor and Foyer, 1998). The present section describes the status of the production of ROS, the induction of oxidative stress, and the roles of individual components of the antioxidative defense system under various abiotic stresses.

### 5.4.1 DROUGHT

Among the stressful conditions of the environment, drought serves as major constraint, limiting crop production in arid and semiarid areas of the world. Growth and the primary production of plants are severely reduced by water deficit (Tambussi et al., 2000; Fatima et al., 2005). The inhibition of carbon dioxide ( $\text{CO}_2$ ) assimilation, coupled with the changes in photosystem activities, and photosynthetic transport capacity under drought stress result in the accelerated production of ROS *via* the chloroplast Mehler reaction (Asada, 1999). ROS enhancement under drought stress functions as an alarm signal that triggers acclimatory/defense responses by specific signal transduction pathways that involve  $\text{H}_2\text{O}_2$  as secondary messenger. ROS signaling is linked to abscisic acid (ABA),  $\text{Ca}^{2+}$  fluxes, and sugar sensing, and is likely to be involved both upstream and downstream of the ABA-dependent signaling pathways under drought stress. Nevertheless, if drought stress is prolonged above a certain extent, ROS production will overwhelm the scavenging action of the antioxidant system, resulting in extensive cellular damage and death (de Carvalho, 2008). Root is the first plant organ to sense reduced water supply. Signals are generally sent from roots to the leaves through the xylem sap, and the phytohormone abscisic acid is considered to be one of the major root-to-shoot stress signals. After reaching leaves, stress signals trigger stomatal closure and the plant shifts to a water-saving strategy. By adjusting stomatal opening, plants control water loss by reducing the transpiration flux, but the entrance of  $\text{CO}_2$  is also reduced concomitantly. Limited supply of  $\text{CO}_2$  to chloroplasts causes lack of electron acceptors. As a result, the electron transport chain is over reduced and the production of ROS increases. The limitation on  $\text{CO}_2$  fixation reduces  $\text{NADP}^+$  regeneration, leading to an over reduction of the photosynthetic electron transport chain. Thus, during water deficit, there is a considerable potential

for increased accumulation of  $O_2^{\cdot-}$  and  $H_2O_2$  resulting from the increased rate of  $O_2$  photoreduction in chloroplasts (Robinson and Bunce, 2000). A higher leakage of electrons to  $O_2$  by the Mehler reaction has been observed in plants subjected to drought stress. Biehler and Fock (1996) reported 50% more leakage of photosynthetic electrons to the Mehler reaction in drought-stressed wheat plants, compared to unstressed plants. Increased formation of ROS, lipid peroxidation, and protein modification has been observed in several plant species subjected to drought stress (Boo and Jung, 1999; Sharma and Dubey, 2005; Bai et al., 2006; Esfandiari et al., 2008). The sequence of events in plant tissues subjected to drought include (1) increased production of ROS and of oxidized target molecules, (2) increase in the expression of genes for antioxidant functions, (3) increase in the levels of nonenzymic and enzymic antioxidants etc., (4) resulting in the tolerance against drought stress (Mano et al., 2002). Drought stress increases the specific activity of some of the antioxidant enzymes and also induces the synthesis of new isoenzymes to overcome the increased oxidative stress (Srivalli et al., 2003; Sharma and Dubey, 2005). Enhanced activity of enzymes of antioxidative defense system has been reported under drought stress in *Zea mays* (Jagtap and Bhargava, 1995), *Oryza sativa* (Boo and Jung, 1999; Sharma and Dubey, 2005), *Triticum durum* (Sgherri et al., 2000), and *Camellia sinensis* (Rajamickam et al., 2005) plants. The degree to which the activities of antioxidant enzymes and the amount of antioxidants increase in drought-stressed plants appears to be extremely variable among several plant species, even between different cvs. of the same species. Reddy et al. (2004) observed that among five mulberries (*Morus alba* L.) cultivars (BC2-59, K-2, MR-2, S-13, and TR-10) subjected to drought, cvs. S-13 and BC2-59 had efficient antioxidative characteristics that could provide better protection against oxidative stress in leaves under water-limited conditions. Compared to drought-sensitive maize genotype (Trihybrid 321), the drought-tolerant maize genotype (Giza 2) exhibited lower accumulation of MDA and  $H_2O_2$  content and increased activities of antioxidant enzymes SOD, CAT, and POD under water stress (Moussa and Abdel-Aziz, 2008). Differential responses for antioxidative enzymes SOD and POD to progressive drought stress were also found between the two contrasting populations (wet climate and dry climate population) of *Populus cathayana* Rehder. One of the reasons for difference in drought tolerance was suggested to be the increased capacity of the antioxidative system to scavenge ROS, and the consequent suppressed level of lipid peroxidation under drought conditions (Xiao et al., 2008a). The response of a plant species to drought not only depends on the species inherent “strategy” but also on the duration and severity of the drought period. Activities of SOD and CAT increased in response to severe water deficit in mature leaves of *Populus deltoides* × *nigra* clones, “Luisa Avanzo,” and “Dorskamp.” For both clones, three different SOD isoforms, Mn-SOD, Fe-SOD, and Cu/Zn-SOD were detected in varying amounts depending on drought intensity (Marron et al., 2006). An increase in the amount of AsA and GSH was observed as the level of drought stress was intensified in two widely cultivated cvs. of wheat in Iran, Sab., and N. Sar. (Esfandiari et al., 2008). In rice plants, increase in the capacity of AsA regeneration system by *de novo* synthesis of MDHAR, DHAR, and GR has been shown to be one of the primary responses to water deficit so as to mitigate oxidative stress (Boo and Jung, 1999; Sharma and Dubey, 2005). APX serves as an important component of antioxidative defense system under drought (Sharma and Dubey, 2005).

Al-Ghamdi (2009) showed the ability of wheat plants to acclimatize and induce the antioxidant defense system under drought stress. The drought-acclimated leaves exhibited systematic increase in the activity of  $H_2O_2$ -scavenging enzymes, particularly APX and CAT, and maintained adequate AsA redox pool by the efficient functioning of APX enzyme. As a result, lower membrane injury and a lower MDA content was observed in drought-acclimated plants (Al-Ghamdi, 2009).

#### 5.4.2 SALINITY

Soil salinity is one of the most serious constraints to crop productivity, especially in the arid and semiarid regions of the world. High concentrations of soluble salts in the soil environment cause nutrient imbalance, water deficit, and toxicity of salt ions in growing plants. Therefore, plants growing in saline soils have to encounter two types of stresses, osmotic stress and ion toxicity

(Lin and Kao, 2001; Munns, 2002). High salt concentrations normally impair the cellular electron transport and lead to the overproduction of the ROS- $O_2^{\cdot-}$ ,  $\cdot OH$ ,  $H_2O_2$ , and  $^1O_2$ . Several reports have demonstrated that salinity stress results in an excessive generation of these ROS (Tanou et al., 2009). Some researchers suggest that stomatal closure upon salt stress may limit the entry of  $CO_2$ , which, in turn, may cause the over reduction of photosynthetic electron transport system. Elevated  $CO_2$  mitigates the oxidative stress caused by salinity, involving lower ROS generation and a better maintenance of redox homeostasis as a consequence of higher assimilation rates and lower photorespiration (Perez-Lopez et al., 2009). NaCl-induced production of  $H_2O_2$  was likely linked to NAD(P)H-oxidase and amine oxidase regulation and was suggested to be signaled by nitric oxide (NO), salicylic acid (SA), protein kinase, and  $Ca^{2+}$  channel activity (Tanou et al., 2009). Enhanced production of ROS under salinity stress induces phytotoxic reactions such as lipid peroxidation, protein degradation, and DNA mutation (Hefny and Abdel-Kader, 2009; Tanou et al., 2009). The effects of salinity on cellular oxidative metabolism were analyzed in strawberry (*Fragaria x ananassa* Duch., cv. Selva) leaves. It was found that NaCl induced oxidative stress in strawberry leaves, as evidenced by an  $H_2O_2/O_2^{\cdot-}$  accumulation, an increase in lipid peroxidation and carbonyl groups content. NaCl caused the oxidation of AsA and GSH redox pairs and inhibition in the activities of some ROS-metabolizing enzymes including CAT, APX, GR (Tanou et al., 2009). In olive plants (*Olea europaea*), salinity was shown to induce NADPH-producing dehydrogenases in order to recycle NADPH necessary for the protection against oxidative damages. These NADP-dehydrogenases appear to be key antioxidative enzymes in olive plants under salt stress conditions (Valderrama et al., 2006).

The effect of salt stress depends on the organ of the plant, developmental stage of the plant, genotypes of the plant species, as well as the intensity and duration of the stress. Pronounced organ specificity of antioxidant defense system functioning was observed in *Plantago major* L. subjected to NaCl. The roots were characterized by high constitutive activities of SOD and three forms of peroxidase, and a lower CAT activity. Unlike leaves, the roots of *P. major* under salinity conditions possessed a higher activity of the antioxidant system, protecting plants from injurious action of oxidative stress, thereby providing the survival of this plant species under stress conditions (Radyukina et al., 2009). Salinity levels of 50 and 100 mM NaCl induced significant increase in SOD activity, GSH levels, and carotenoid concentrations in all tolerant genotypes and the local genotype of forage sorghum seedlings compared to sensitive group. It was suggested that these antioxidants can be considered as selection criteria for salt tolerance in sorghum species (Hefny and Abdel-Kader, 2009). Antioxidant systems depend on cultivars and cropping seasons. The antioxidant system in salt-stressed summer crop cultivars of "House Momotaro" was attributed to the enzymatic reactions of APX and GR, while in salt-stressed "Mini Carol" crop, it was attributed to the nonenzymatic reactions of AsA and GSH. In the winter crop, the antioxidant systems were not influenced by salt stress in either cultivar. The seasonal- and cultivar-specific differences of salt-induced changes in the antioxidant systems may result from differences in antioxidant capacities and the interaction between salt stress and growth conditions such as temperature and solar radiation (Zushi and Matsuzoe, 2009).

The changes in the leaf apoplastic antioxidant defenses in response to NaCl stress has been studied in two pea (*Pisum sativum*) cvs. Lincoln and Puget showed the different degrees of sensitivity to high NaCl concentrations. The results showed that SOD, AsA, GSH and, probably, DHAR were present in the leaf apoplastic space, whereas APX, MDHAR, and GR seemed to be absent. The AsA/DHA and GSH/GSSG ratios decreased progressively with the severity of the stress. Apoplastic SOD activity was induced in NaCl-treated pea cv. Puget but decreased in NaCl-treated pea cv. Lincoln. An increase in DHAR and GR and a decrease in APX, MDHAR, AsA, and GSH levels was observed in the symplast from NaCl-treated pea cv. Lincoln, whereas in pea cv. Puget, an increase in DHAR, GR, and MDHAR occurred. These results suggested a strong interaction between both cell compartments in the control of the apoplastic AsA content in pea leaves. Both the different antioxidative capacity and the NaCl-induced response in the apoplast and in the symplast from pea cv. Puget in comparison with pea cv. Lincoln was suggested to contribute to a better protection of pea cv. Puget against salt stress (Hernandez et al., 2001).

Using DNA microarray, Kawasaki et al. (2001) showed the salt-induced upregulation of several antioxidant genes in rice roots. Studies suggest that CAT, POD, and SOD isoenzymes can serve as useful markers in the analysis of gene functions and metabolic regulations, including salt-tolerance characteristics (Mittal and Dubey, 1991; Piqueras et al., 1996; El-baky et al., 2003). The specific activities and patterns of CAT, POD, and SOD isoenzymes are altered significantly in plants subjected to salinity stress. The induction of a new SOD isozyme was found in salt-tolerant embryonic callus cultures of lemon (*Citrus limon* L. Burn) (Piqueras et al., 1996). Rice seedlings, differing in salt tolerance, possess constitutively different number of peroxidase isoforms in nonsalinized seedlings. When these seedlings were raised under NaCl salinity, certain new isoforms of peroxidases appeared, and the intensities of some of the preexisting isoenzymes increased. In 15-day-old seedlings of a salt-tolerant rice cv. CSR-1, three isoenzymes were observed in roots and five in shoots, whereas in a salt-sensitive cv. Ratna, six isoenzymes were observed in the roots as well as in shoots (Mittal and Dubey, 1991). Similarly, electrophoretic bands of POD and CAT isoenzymes of onion cultivars were found to vary in numbers and relative concentrations due to salts stress. New protein bands and the characteristic CAT and POD isoenzymes banding patterns have been suggested as a biochemical marker for the selection of salt-tolerant plants (El-baky et al., 2003).

Changes in the activities of antioxidant enzymes and the levels of some nonenzymatic antioxidants were assessed for their use as markers of salt tolerance in nine genetically diverse pea (*Pisum sativum*) cvs. Salt stress markedly enhanced the activities of SOD and POD, as well as the levels of total phenolics and  $\gamma$ - and  $\delta$ -tocopherols, and decreased the total soluble proteins and CAT activity, while the internal levels of  $H_2O_2$  remained unaffected in all pea cvs. Of different antioxidant enzymes and metabolites analyzed, only CAT activity was found to be a reliable marker of salt tolerance in pea cultivars examined (Noreen and Ashraf, 2009).

The tolerance of *Physcomitrella patens* for high-salinity environments makes it an ideal candidate for studying the molecular mechanisms by which plants respond to salinity stresses. Differential genomic and proteomic screenings carried out in these plants showed that plants responded to salinity stress by upregulating a large number of genes involved in antioxidant defense mechanism (Wang et al., 2008), suggesting that the antioxidative system may play a crucial role in protecting cells from oxidative damage following exposure to salinity stress in *P. patens*.

### 5.4.3 HEAT

High temperature is becoming one of the significant abiotic stresses limiting plant growth and productivity, especially as the global temperature is likely to increase by 1.5°C–4.5°C by 2050 (Houghton et al., 2001). The damage to plants exposed to heat stress has been ascribed to the inhibition of photosynthesis, damage to cell membrane, senescence, and cell death (Xu et al., 2006). ROS could play a key role in mediating important signal transduction events. The rates and cellular sites of ROS production during high temperature or heat stress could play a central role in stress perception and protection. ROS levels, as well as ROS signals, are thought to be controlled by the ROS gene network of plants. It is likely that in plants, this network is interlinked with the different networks that control heat stress acclimation and tolerance. Suzuki and Mittler (2006) propose a model for the involvement of ROS in heat stress sensing and defense. Heat stress leads to the overproduction of ROS in the cells (Bukhov et al., 1999; Yin et al., 2008). Ribulose biphosphate carboxylase/oxygenase (Rubisco) can lead to the production of  $H_2O_2$  as a result of its oxygenase reactions and such  $H_2O_2$  production substantially with temperature (Kim and Portis, 2004). A considerable amount of work has revealed high temperature-induced oxidative damages in plants (El-Shintinawy et al., 2004; Yin et al., 2008). Lipid peroxidation level was directly correlated with temperature and exposure time in the seedlings of two Egyptian cultivars of barley (Giza 124 and 125). Heat shock caused an increase in the electrical conductivity of cell membrane and increased MDA content coupled with the disappearance of the polyunsaturated linolenic acid ( $C_{18:3}$ ) in the seedlings, reflecting the peroxidation of membrane lipids, which led to the loss of membrane selective

permeability (El-Shintinawy et al., 2004). Plant survival under heat stress requires the activation of proper defense mechanisms to avoid oxidative stress. Wheat genotypes HD 2815 and HDR-77 showed relatively higher SOD, APX, GR, CAT, and POX activity compared to PBW 343, PBW 175, and HD 2865 under high temperature stress. Genotypes showing highest activity of various antioxidant enzymes also showed minimum reduction in chlorophyll content and lower membrane injury index, indicating the amelioration of high temperature stress-induced oxidative stress by antioxidant enzymes (Almeselmani et al., 2006).

The antioxidant response depends on the severity and duration of the stress. When the effects of high temperature on antioxidant enzymes were investigated in three mulberry (*Morus alba* L.) cvs. K-2, MR-2, and BC2-59 maintained at 40°C for 120, 240, and 360 min., the activities of SOD, CAT, POD, APX, and GR increased with the duration of heat stress in all three cultivars. Cultivar BC2-59 showed efficient antioxidant system among the three cultivars, which could prevent the oxidative damage in the leaves caused due to high temperature stress (Chaitanya et al., 2002). El-Shintinawy et al. (2004) showed heat-induced distinct and significant changes in activities of antioxidant enzymes in barley. SOD and POD activities were progressively enhanced by moderate and elevated heat doses, but the most elevated one (45°C for 8 h) showed a decrease in activities of both enzymes. In contrast, CAT activity was reduced with all heat shocks (El-Shintinawy et al., 2004). In lily (*Lilium longiflorum* L.) plants, exposure to 37°C and 42°C for 10 h caused stimulation in the activities of antioxidant enzymes SOD, POD, CAT, APX, and GR and elevated levels of AsA and GSH, which resulted in low levels of  $O_2^{\cdot-}$  and  $H_2O_2$  concentrations. However, after 10 h exposure at 47°C, activities of SOD, APX, and GR, as well as the concentration of GSH were similar to the controls, while activities of POD, CAT and AsA concentration declined significantly as compared to the control, with a concomitant increase in  $O_2^{\cdot-}$  and  $H_2O_2$  concentrations. In addition, such heat-induced effects on antioxidant enzymes were also observed with SOD and POD isoforms, as Cu/ZnSOD maintained high stability under heat stress whereas the intensity of POD isoforms decreased with the duration of heat stress, especially at 47°C. Oxidative damage induced by heat stress was related to the changes in antioxidant enzyme activities and levels of antioxidants (Yin et al., 2008).

In plants, the AsA–GSH cycle plays a pivotal role in controlling ROS levels and cellular redox homeostasis. When AsA–GSH cycle enzymes were analyzed in the cytosol, mitochondria, and plastids of tobacco Bright Yellow-2 cultured cells subjected to two different heat shocks, it was observed that moderate heat shock (35°C) did not affect cell viability, whereas exposure of cells to 55°C led to heat shock-induced programmed cell death (PCD). In relation to AsA–GSH cycle, the three analyzed compartments appeared to have specific enzymatic profiles that were diversely altered by the heat shock. The cytosol contained the highest activity of all AsA–GSH cycle enzymes, in particular, the cytosolic APX was found to be the most versatile enzyme, the activity of which was enhanced after moderate heat shock and declined during PCD induction, whereas other APX isoenzymes were affected only in the cells undergoing PCD (Locato et al., 2009).

#### 5.4.4 CHILLING

Chilling stress is a key factor limiting the survival of plants and their geographical distribution. Susceptibility to chilling injury prevents the cultivation of many crops in regions where temperatures can drop much below the optimal growth temperatures (Ercoli et al., 2004). Chilling stress causes both preharvest and postharvest damage to plants, which results in enormous yield losses every year. Evidences suggest that chilling stress in plants leads to increased formation of ROS in both roots and leaves. Chilling conditions exacerbate the imbalance between light absorption and light use by inhibiting Calvin–Benson cycle activity (Logan et al., 2006). Enhanced photosynthetic electron flux to  $O_2$  and the over-reduction of respiratory electron transport chain resulting in ROS accumulation has been shown in cucumber leaves subjected to chilling (Hu et al., 2008). Oxidative stress has been suggested to be a significant factor in relation to chilling injury in plants. Chilling-associated oxidative damage that enhances the production of ROS slows down metabolism and

causes the peroxidation of membrane lipids and results in a significant increase in MDA content. The chilling of *Arabidopsis thaliana* (L.) Heynh. callus tissues to 4°C led to conditions of oxidative stress, as indicated by increased levels of the products of peroxidative damage to cell membranes (O’Kane et al., 1996). Evidence for chilling-induced oxidative stress has also been observed in maize seedlings (Prasad et al., 1994).

Responses to chilling-induced oxidative stress include alteration in the activities of enzymes of antioxidant defense system. In leaves of strawberry plantlets under low temperature treatment, the rates of  $O_2^{\cdot-}$  generation and the contents of  $H_2O_2$  and MDA increased and the activities of antioxidant enzymes SOD, CAT, POD, and APX gradually increased to a certain degree and decreased thereafter. Therefore, it is suggested that low temperature stress triggers increased production of ROS in plants, and the early accumulation of ROS might lead to increased activity of antioxidant defense system. If the duration of chilling stress is too long, the defense system may not remove overproduced ROS effectively, which may result in severe damage or even death (Yong et al., 2008). Chilling stress preferentially enhances the activities of the antioxidative enzymes SOD, APX, GR, and GPX, whereas the activity of CAT decreases in the leaves of cucumber seedlings (Lee and Lee, 2000). Nonenzymic antioxidants (AsA, GSH, and carotenoids) also play an important role in cold response. Under cold stress conditions, the content of low-molecular-weight antioxidants, especially that of reduced AsA, increases in barley seedlings. After the termination of stress, the contents of total AsA, GSH, and carotenoids get reduced to the level close to the initial one. Though the level of reduced AsA declines, it remains at the level higher than the initial. Therefore, reduced AsA has been suggested to be an important component in plant cell defense during low temperature treatment (Radyuk et al., 2009).

ROS producing and scavenging systems are found in various organelles. Radyuk et al. (2009) observed more active cytoplasmic SOD than its chloroplast isoforms in green barley (*Hordeum vulgare* L.) seedlings, suggesting that oxidative process initiation under low temperature stress occurred more actively in the cytosol compared to the chloroplasts. The response timing of different antioxidant enzyme isoforms to chilling was found to be different in leaves of cucumber seedlings. Out of five APX isoforms present in leaves, the intensities of APX-4 and -5 were enhanced by chilling stress, whereas that of APX-3 was significantly increased in the poststress periods after chilling stress. Expressions of Mn-SOD-2 and -4 were enhanced only after 48 h of the poststress period. All six GR isoforms showed increased intensity in stressed plants compared to the control and poststressed plants (Lee and Lee, 2000).

Cold treatment may initially cause injury, but during the recovery period, leaves coordinate and enhance the capacity of the antioxidative system, to diminish the potential of active oxygen species (Bafeel and Ibrahim, 2008). In lucerne leaves, after dark chilling treatment, a marked increase in the level of  $H_2O_2$  and MDA was observed (Bafeel and Ibrahim, 2008). After recovery period, the MDA content decreased significantly due to the increase of phenolic compounds, which suppressed lipid peroxidation. Also, the redox properties of  $\alpha$ -tocopherol play an important role in adsorbing and neutralizing free radicals and provide some forms of antioxidant protection. The activity of SOD increased sharply with the imposition of chilling stress, whereas CAT, APX, and GR activities slightly increased with the imposition of chilling. During the recovery period, activities of CAT, APX, and GR increased significantly, which could possibly restrict the recycling of active oxygen species associated with chilling stress (Bafeel and Ibrahim, 2008). Radyuk et al. (2009) concluded that APX and CAT play an important role in plant cell defense against low temperatures, whereas reduced GR and SOD activities are especially important during poststress period in barley seedlings.

Acclimation to prolonged chilling stress can be achieved by briefly pre-exposing the plants to low nonfreezing temperatures, a process called cold acclimation (CA). For a chilling-sensitive crop like maize, low temperature treatment during the early stages of development can be detrimental to subsequent crop establishment and productivity (Stewart et al., 1990; Greaves, 1996). Acclimation-induced CAT seems to play a major role, probably along with other antioxidant enzymes, in inducing chilling tolerance in pre-emergent maize seedlings (Prasad, 1997).

### 5.4.5 METAL TOXICITY

High concentrations of essential as well as nonessential metals in the soil environment, arising from mining and industrial activities, disposal of sewage sludge or soil acidification, and use of pesticides and fertilizers, continues to be a serious risk for plant health (Barcelo and Poschenrieder, 1990). Soil contamination with a variety of metals has become a global problem, leading to losses in agricultural yield (Salt et al., 1995). These metals are taken up from the soil by growing plants, and one of the consequences of the presence of the toxic metals within the plant tissues is the formation of free radical species, which can be initiated directly or indirectly by the metals and, consequently, lead to oxidative damage to different cell constituents (Gallego et al., 2002). Metal toxicity for living organisms involves oxidative and/or genotoxic mechanisms (Briat and Lebrun, 1999). Enhanced generation of ROS can overwhelm cells' intrinsic antioxidant defenses, and may result in a condition known as "oxidative stress." Recent studies indicate that transition metals act as catalysts in the oxidative reactions of biological macromolecules; therefore, the toxicities associated with these metals might be due to oxidative tissue damage. Both redox-active as well as redox-inactive metals cause an increase in the production of ROS such as  $O_2^{\cdot-}$ ,  $\cdot OH$ ,  $H_2O_2$ . Redox-active metals, such as iron, copper, and chromium, undergo redox cycling, whereas redox-inactive metals, such as lead, cadmium, mercury, and others deplete cell's major antioxidants, particularly thiol-containing antioxidants and enzymes (Gallego et al., 1996; Weckx and Clijsters, 1996; Yamamoto et al., 1997; Shah et al., 2001; Verma and Dubey, 2003; Sharma and Dubey, 2007; Maheshwari and Dubey, 2009). If metal-induced production of active oxygen species is not adequately counterbalanced by cellular antioxidants, the oxidative damage of lipids, proteins, and nucleic acids ensues (Halliwell and Gutteridge, 1989; Dat et al., 2000; Sharma and Dubey, 2007; Sandalio et al., 2009; Sharma and Dietz, 2009). A significant decline in protein thiol content is observed when rice seedlings are subjected to Al or Ni toxicity (Sharma and Dubey, 2007; Maheshwari and Dubey, 2009). In addition to the use of plant seedlings or adult plants, another interesting approach has been the use of *in vitro* cell cultures to study plant responses to abiotic stresses, more importantly metal toxicities (Gomes-Júnior et al., 2006). The induction of ROS production with heavy metals (cadmium and zinc) in *Nicotiana tabacum* L. cv. Bright Yellow 2 (TBY-2) cells in suspension cultures showed properties comparable to the elicitor-induced oxidative burst in other plant cells (Zrobek-Sokolnik et al., 2009). These heavy metals generated  $O_2^{\cdot-}$ ,  $H_2O_2$ . The effects of CAT, N,N-diethyldithiocarbamate (DDC), and SOD on the heavy metal-induced ROS production indicated that it occurs outside of the cells, and that at least part of the  $H_2O_2$  is produced by the dismutation of the  $O_2^{\cdot-}$ . Results suggested that the enzyme responsible for cadmium and zinc-induced ROS generation in tobacco cells contains a flavocytochrome (Zrobek-Sokolnik et al., 2009).

The increased activity of antioxidative enzymes in metal-stressed plants appears to serve as an important component of antioxidant defense mechanism of plants to combat metal-induced oxidative injury (Shah et al., 2001). Antioxidant system consisting of several nonenzymic and enzymic components is activated in the cells as a response to metal stress (Gallego et al., 1996; Shah et al., 2001; Verma and Dubey, 2003). Activation of antioxidant enzymes like POD, SOD, APX and enzymes of AsA-GSH cycle due to the toxicity of metals like Cd, Pb, Al, have been reported in plants by various groups of workers (Cakmak and Horst, 1991; Shah et al., 2001; Verma and Dubey, 2003; Sharma and Dubey, 2007). However, results suggest that the activation of antioxidant enzymes in response to oxidative stress induced by metals is not enough to confer tolerance to metal accumulation. Responses of heavy metal exposure to plants vary depending on plant species, tissues, stages of development, type of metal and its concentration. One of the key responses includes the triggering of a series of defense mechanisms that involve enzymatic and nonenzymatic components (Gratão et al., 2005). Among various metals like Cd, Pb, Al, and the metalloid As, different effects have been observed on plant metabolism, and although roots are regarded as the main sites of metal accumulation, the oxidative damage was found to be more detrimental in the leaves (Erdei et al., 2002; Jha and Dubey, 2004; Sharma and Dubey, 2007).

$\text{Cu}^{2+}$  ions are redox active and catalyze Fenton-type reactions producing  $\cdot\text{OH}$  (Elstner et al., 1988). Lipid peroxides also originate from the induction of the enzyme lipoxygenase in the presence of  $\text{Cu}^{2+}$  (Somashekaraiah et al., 1992). This enzyme is known to initiate lipid peroxidation. Iron has a pivotal and dual role in free radical chemistry in all organisms. Free Fe can participate in Fenton reactions and can catalyze the generation of  $\cdot\text{OH}$  and other toxic oxygen species. On the other hand, Fe is a constituent of the antioxidant enzymes CAT, APX, GPX, and Fe-SOD (Becana et al., 1998). When plants are exposed to a variety of adverse environmental conditions, including chilling, high light, drought, etc., oxidative stress occurs primarily due to the increase in free radical production mediated by catalytic Fe (Arora et al., 2002), and also due to decrease in antioxidative defense system (Arora et al., 2002).

Arsenic toxicity has been known for centuries, and has recently received increased attention because of its chronic and epidemic effects on human health (Abernathy et al., 1999). Plants normally take up arsenic predominantly in trivalent (AsIII) and pentavalent (AsV) forms, which are known to interfere with various metabolic pathways in cells, like, interaction with sulfhydryl groups, replacement of phosphate from ATP, and the excessive production of ROS. Singh et al. (2007) showed that As induces oxidative stress resulting from enhanced lipid peroxidation in mung bean (*Phaseolus aureus* Roxb.). The accumulation of MDA in seedlings increased significantly with increasing arsenic concentration (both AsIII and AsV). However, oxidative stress was more pronounced in As(III) treatment. The As treatments significantly increased the activities of antioxidant enzymes (SOD and GR) and the contents of antioxidant metabolites (GSH and AsA) in Indian mustard, the increase being dependent on exposure time. Increase in the activity of CAT was not significant. It was concluded that Indian mustard was able to detoxify the low As level through the induction of antioxidant defense mechanism (Khan et al., 2009). The upregulation of APX and POD has also been reported in As(III)/As(V) treatments. Both GSH and Cys imparted enhanced tolerance to seedlings against arsenic stress. Seedlings growth improved while the level of MDA declined significantly when GSH and Cys were supplemented to As(III)/As(V) treatments, suggesting GSH- and Cys-mediated protection against oxidative stress (Shri et al., 2009). While As (V) predominantly stimulates antioxidant enzyme activity, As (III) primarily causes enhanced levels of thiols (Srivastava et al., 2007).

Cadmium is a potent heavy metal pollutant of the environment. It is a heavy metal of widespread occurrence. Cadmium induces oxidative stress in several plant species and increases the activity of enzymes of antioxidant defense system (Shah et al., 2001; Metwally et al., 2003). Lipids that contain phosphate groups are essential components of membrane that surround the cell as well and other cellular structures, such as the chloroplast, mitochondria, and nucleus. Cd-induced oxidative damage involves the peroxidation of PUFA of membrane lipids due to ROS generated by Cd (Lin et al., 2007). Lipid peroxidation eventually increases membrane fluidity and membrane permeability. Elevated levels of lipid peroxides were observed in Cd-stressed rice seedlings (Shah et al., 2001). Under 500  $\mu\text{M}$  Cd treatment, about 1.4 to 1.6 times increase in MDA content was observed, indicating enhanced peroxidation of lipids due to Cd exposure (Shah et al., 2001). The increased production of ROS under Cd toxicity serves as a major source of DNA damage leading to strand breakage, removal of nucleotides, and a variety of modifications in the organic bases of nucleotides (Sarkar, 1995). A distinct pattern of DNA fragmentation, typical for PCD was observed in Cd-exposed tobacco cells (Fojtova and Kovarik, 2000). DNA damage was suggested to be an important mechanism of Cd phytotoxicity in *Vicia faba* plants (Lin et al., 2007). Cadmium treatment decreases chlorophyll and heme levels of germinating mung bean seedlings by the induction of lipoxygenase with the simultaneous inhibition of antioxidative enzymes, SOD and CAT (Somashekaraiah et al., 1992). Such inhibition results from the binding of the metal to the important sulfhydryl group of enzymes, which increases the phytotoxic action of metals (Van Assche and Clijsters, 1990). In pea plants, Cd toxicity induced carbonylation in proteins and the extent of carbonylation was greater in peroxisomes than in the whole plant (Romero-Puertas et al., 2002). Increased protein oxidation was observed in cucumber seedlings (*Cucumis sativus* L.) grown in increasing Cd levels. The importance of the

enzymatic and nonenzymatic antioxidant system in response to Cd toxicity has been shown by several authors. Enhancement in the activities of SOD, CAT, POD, and GR is observed in Cd-stressed rice seedlings (Shah et al., 2001). The activity of another antioxidative enzyme CAT increased in rice seedlings grown at moderately toxic Cd (100  $\mu$ M) level, whereas with highly toxic Cd (500  $\mu$ M) level, a marked inhibition in CAT activity was noted (Shah et al., 2001). Decline in CAT activity in plants growing under higher levels of Cd was suggested due to the inhibition of enzyme synthesis or a change in the assembly of enzyme subunits (Shah et al., 2001). Barley seedlings exposed to 25  $\mu$ M Cd showed increased activity of H<sub>2</sub>O<sub>2</sub>-metabolizing enzymes, CAT and APX (Metwally et al., 2003). Apparently, it is the oxidative stress induced by Cd that enhances the activities of stress-related enzymes by increasing the levels of free radicals and peroxides. Activity of APX was inhibited while the activities of CAT and SOD were increased in cucumber seedlings (*Cucumis sativus* L.) grown in increasing Cd levels. Simultaneously, AsA and nonprotein thiol groups were also found to increase (Gonçalves et al., 2007). A comparison of closely related plant species with different degrees of sensitivity to toxic metals has established a link between the degree of plant tolerance to metals and the level of antioxidants (Sharma and Dietz, 2009). Nouairi et al. (2009) showed that *Brassica juncea* plants possessed greater potential for Cd accumulation and tolerance than *Brassica napus* plants. *Brassica napus*, on Cd exposure, exhibited an increased level of lipid peroxidation, whereas in *Brassica juncea* treated plants, MDA content remained unchanged. In *Brassica napus*, with the exception of GPX, activity levels of some antioxidant enzymes involved in the detoxification of ROS, including SOD, CAT, GR, and APX, decreased drastically at high Cd concentrations. By contrast, in leaves of Cd-exposed *Brassica juncea* plants, there was either only little or no change in the activities of the antioxidative enzymes. Analysis of the profile of anionic isoenzymes of GPX revealed qualitative changes occurring during Cd exposure for both species. The mung bean genotypes (Pusa 9531, Pusa 9072, Pusa Vishal and PS-16) treated with Cd (0, 25, 50, and 100 mg/kg soil) showed a differential response to Cd concentrations; Pusa 9531 was identified as Cd tolerant, whereas PS 16 was Cd susceptible. The results revealed the presence of a strong antioxidant defense system (elevated activities of SOD, CAT, APX, and GR, and the increased amounts of AsA and GSH) in the Cd-tolerant genotype (Pusa 9531) for providing adequate protection against oxidative stress induced by Cd (Anjum et al., 2008).

Aluminum is a major constraint, reducing crop productivity in acid soils throughout the world (Kochian, 1995; Pereira et al., 2006). Although Al itself is not a transition metal and cannot catalyze redox reaction, the involvement of oxidative stress in Al toxicity has been suggested in many plant species. Even without an external supply of Fe, enhanced peroxidation of lipids is observed due to Al in pea (*Pisum sativum*) roots (Yamamoto et al., 2001). Al ions have a strong affinity for biomembranes and cause the rigidification of membranes (Deleers et al., 1986), which seems to facilitate the radical chain reaction, enhancing the peroxidation of lipids in phospholipid liposomes (Oteiza, 1994), soybean (*Glycine max*) roots (Cakmak and Horst, 1991), and cultured tobacco (*Nicotiana tabacum*) cells (Ono et al., 1995; Yamamoto et al., 1997). The Al-induced peroxidation of lipids leads to loss of plasma membrane integrity and eventually cell death in cultured tobacco cells (Yamaguchi et al., 1999). Boscolo et al. (2003) observed a higher degree of protein oxidation in maize roots compared to lipid peroxidation, in Al-treated plants and suggested that in maize roots proteins are the primary target of damage due to ROS under Al toxicity. Sharma and Dubey (2007) also observed the increased modification of proteins in rice seedlings subjected to Al toxicity. Al treatment led to DNA fragmentation in rice seedlings (Meriga et al., 2004). Signaling pathways involving H<sub>2</sub>O<sub>2</sub> cause PCD in heavy metal-stressed plants. Cells treated with 100  $\mu$ M AlCl<sub>3</sub> showed typical features of PCD such as nuclear and cytoplasmic condensation in tomato (*Lycopersicon esculentum* Mill.) suspension cells. Cell death was suppressed by the application of antioxidants and by inhibitors of phospholipase C (PLC), phospholipase D (PLD), and ethylene signaling pathways. The results suggest that low concentrations of heavy metal ions stimulate both PLC and PLD signaling pathways, leading to the production of ROS and subsequent cell death executed by caspase-like proteases (Yakimova et al., 2007).

As Al induces the expression of diverse genes in plant species like wheat, maize, sugarcane, tobacco, *Arabidopsis* and many of these genes encode antioxidant enzymes such as glutathione S-transferase, peroxidase, SOD (Ezaki et al., 2000; Simonovicova et al., 2004). A strong correlation has been suggested between Al toxicity and oxidative stress in plants (Richards et al., 1998; Boscolo et al., 2003; Watt, 2004). Ezaki et al. (2000) confirmed this hypothesis when they showed that over-expression of some Al-induced genes in transgenic *Arabidopsis* plants conferred oxidative stress resistance. Meriga et al. (2004) found a close inverse relationship between decreased root growth and increased Al accumulation, lipid peroxidation, SOD and POD activities, and DNA damage in rice plants. Higher activities of SOD and POD in Al-stressed rice seedlings suggested that these enzymes could serve as efficient free radical scavengers to minimize the adverse effects of lipid peroxidation and could contribute to the maintenance of membrane structure and the integrity of rice plants under Al toxicity. According to Sharma and Dubey (2007), Al toxicity is associated with the induction of oxidative stress in rice plants, and among antioxidative enzymes, SOD, guaiacol POX, and cytosolic APX appear to serve as important components of antioxidative defense mechanism under Al toxicity. Polyacrylamide gel electrophoresis (PAGE) confirmed the increased activity as well as the appearance of new isoenzymes of APX in Al-stressed seedlings. Immunoblot analysis revealed that changes in the activities of APX are due to changes in the amounts of enzyme protein (Sharma and Dubey, 2007).

Lead is one of the major heavy metals of antiquity and has gained considerable importance as a potent environmental pollutant (Sharma and Dubey, 2005). One of the phytotoxic effects of Pb appears to be the induction of oxidative stress in growing plant parts due to the enhanced production of ROS resulting in unbalanced cellular redox status. Pb is not a oxido-reducing metal like iron, therefore, the oxidative stress-induced by Pb in plants appears to be an indirect effect of Pb toxicity leading to the production of ROS, enhancing the pro-oxidant status of the cell by reducing the pool of reduced GSH, activating calcium-dependent systems, and affecting iron-mediated processes (Pinto et al., 2003). Though the ROS-generating processes are slow under normal conditions, Pb accelerates them (Verma and Dubey, 2003). Such production depends on the intensity of stress, repeated stress periods, species and age of plants (Asada, 1994; Verma and Dubey, 2003). Pea plants treated with Pb showed the increased level of the ROS  $O_2^{\cdot-}$  and  $H_2O_2$  in the roots and the increase was proportional to metal concentration (Malecka et al., 2009). Lipid peroxidation, which is regarded as an indicator of oxidative damage, involves the oxidative degradation of PUFA residues of membranes (Girotti, 1990). Pb ions induce lipid peroxidation, decrease the level of saturated fatty acids, and increase the content of unsaturated fatty acids of membrane in several plant species (Halliwell and Gutteridge, 1999; Verma and Dubey, 2003; Reddy et al., 2005). MDA level was reported to increase concomitantly with the increasing level of  $H_2O_2$  produced in pea plants treated with Pb (Malecka et al., 2009). When rice (*Oryza sativa*) seedlings were raised in sand cultures under 500 and 1000  $\mu M$   $Pb(NO_3)_2$  in the medium, during a growth period of 5–20 days, about 21%–177% increase in the level of lipid peroxides was observed, indicating that Pb induces oxidative stress in rice plants (Verma and Dubey, 2003).

The importance of antioxidant defense mechanism to tolerate oxidative stress produced by Pb has been shown by various research groups. Activities of the antioxidative enzymes SODs, CAT, and APX and the levels of low-molecular antioxidants, particularly GSH, homogluthathione (h-GSH), and cysteine were reported to increase concomitantly with increasing Pb concentration and the duration of treatment (Malecka et al., 2009). The redox state (GSH/GSSG) of root cells dropped proportionally to stress intensity (Malecka et al., 2009). Pb-treated rice seedlings showed increase in the activities of the enzymes SOD, GPX, APX, and GR compared to untreated controls (Verma and Dubey, 2003). A highly toxic concentration of Pb (1000  $\mu M$ ) treatment led to decrease in the intensity of two pre-existing CAT isoforms in shoots of rice seedlings. It is shown that Pb induces oxidative stress in growing rice plants and that SOD, PODs, and GR could serve as important components of antioxidative defense mechanism against Pb-induced oxidative injury in rice plants (Verma and Dubey, 2003). Chloroplasts isolated from spinach seedlings treated with  $PbCl_2$  showed increase in both ROS and MDA content, and reduction in photosynthesis and activities of the antioxidant defense system (SOD, CAT, APX, GPX, and GSH content), indicating that spinach

chloroplasts underwent a stress condition due to an oxidative attack. The results imply that spinach chloroplasts were not able to tolerate the oxidative stress induced by  $\text{Pb}^{2+}$  possibly due to lack of an effective antioxidant defense mechanism (Xiao et al., 2008a).

Nickel is an essential nutrient for plants. However, the amount of Ni required for normal growth of plants is very low. Nickel toxicity has been associated with oxidative stress in plants. Nickel-treated rice seedlings showed increased rates of  $\text{O}_2^{\cdot-}$  production, elevated levels of  $\text{H}_2\text{O}_2$ , and thiobarbituric acid reactive substances (TBARS), demonstrating enhanced lipid peroxidation, and a decline in protein thiol levels indicative of increased protein oxidation compared to controls (Maheshwari and Dubey, 2009). Gajewska and Skłodowska (2007) observed that despite prolonged increases in  $\text{O}_2^{\cdot-}$  and  $\text{H}_2\text{O}_2$  levels, oxidative damage measured in terms of lipid peroxidation, did not occur in the leaves of Ni-treated wheat plants.

With progressively higher Ni concentrations, nonprotein thiol and AsA levels increased, whereas the level of low-molecular-weight thiols (such as GSH and hydroxyl-methyl GSH), the ratio of these thiols to their corresponding disulfides, and the ratio of AsA to DHA declined in the rice seedlings (Maheshwari and Dubey, 2009). The activities of all isoforms of SOD (Cu-Zn SOD, Mn SOD, and Fe SOD), GPX, and APX were reported to increase in Ni-treated rice seedlings, while no clear alteration in CAT activity could be observed (Maheshwari and Dubey, 2009). Excess supply of Ni was shown to inhibit the CAT activity and induce POD, APX, and SOD activities in maize. Localization of isoforms of these enzymes on native gels also revealed increases in the intensities of pre-existing bands. Enhanced activities of peroxidase, APX, and SOD, however, did not appear to be sufficient to ameliorate the effects of excessively generated ROS due to excess supply of Ni (Kumar et al., 2007). Activity of the AsA-GSH cycle enzymes MDHAR, DHAR, and GR significantly increased in Ni-treated seedlings (Maheshwari and Dubey, 2009). Exposure of Ni to *Nicotiana tabacum* cv. BY-2 cell suspensions led to alterations in isoenzymes of SOD, CAT, and GR. Activity staining analysis revealed that CAT activity plays a major role in the early response to Ni-induced oxidative stress, particularly, when the Ni concentration used is low, while a specific GR isoenzyme appears to respond to the Ni-induced oxidative stress when a much higher Ni concentration is used to induce the stress for the same period of treatment (Pompeu et al., 2008). These results illustrate the importance and advantages of determining individual isoenzyme activities. The differential responses of SOD, CAT, and GR isoenzymes are associated with specific physiological phenomena of the cells due to the specific organellar localization of the isoenzymes (Pompeu et al., 2008).

When wheat seedlings were treated with Ni, a significant increase in  $\text{H}_2\text{O}_2$  concentration was observed in both roots and shoots (Gajewska and Skłodowska, 2008). The constitutive activities of antioxidative enzymes, other than CAT, were much higher in the roots than in the shoots, and Ni application caused several-fold increased activities of APX, POD, and GST in the shoots, whereas in the roots, the activities were not significantly altered. The differential antioxidative responses of the shoots and roots of wheat seedlings to Ni stress might be ascribed to diverse constitutive levels of antioxidant enzyme activities in both the organs (Gajewska and Skłodowska, 2008). When  $\text{H}_2\text{O}_2$  levels were compared in hairy roots of hyperaccumulator species, *Alyssum bertolonii* and the nonhyperaccumulator, *Nicotiana tabacum*, it was found that  $\text{H}_2\text{O}_2$  levels rose significantly with Ni treatment in both species, by factors of 3.6 and 8.6, respectively. Compared with *N. tabacum*, oxidative damage was suggested to be minimized in *A. bertolonii* roots by the high endogenous activities of CAT and, to a lesser extent, SOD (Boominathan and Doran, 2002). Using a transgenic approach, it has been confirmed that antioxidative defense system plays an important role in combating metal-induced oxidative stress in plants (Duan et al., 2006; Guan et al., 2009).

#### 5.4.6 ANAEROBIOSIS

Anaerobic stress is thought to be a major stressful factor in the growth of crop plants in waterlogged soils, as oxygen diffuses 10,000 times more slowly in water than in air (Armstrong, 1979). Oxygen deficiency causes stomatal closure (Crawford, 1978), which reduces  $\text{CO}_2$  availability in the leaves

and inhibits carbon fixation. Thus, excessive excitation energy in chloroplasts could increase the generation of ROS and induce oxidative stress (Gossett et al., 1994). An excessive accumulation of  $O_2^{\cdot-}$  and  $H_2O_2$  is observed in plants subjected to anaerobic stress (Yan et al., 1996; Kumutha et al., 2009; Sairam et al., 2009). Roots suffer from the periodic or prolonged deprivation of oxygen, which leads to diminished respiration at the level of electron transport. The lack of a suitable electron acceptor leads to saturated redox chains, accumulation of NAD(P)H, and a decline in the generation of ATP. Flooding stress also contributes to the accumulation of acetaldehyde and other compounds derived from the anaerobic metabolism, which could be susceptible to degradation, yielding  $H_2O_2$  as an end product (Blokhina et al., 2003). The presence of  $H_2O_2$  in the apoplast and in association with the plasma membrane has been visualized by transmission electron microscopy under hypoxic conditions in yellow flag iris (*Iris pseudacorus*) and rice, and anoxia-intolerant wheat and garden iris (*Iris germanica*) (Blokhina et al., 2001). In the anoxia-tolerant species, the response was delayed in time, and in highly tolerant *I. pseudacorus*, plasma membrane-associated  $H_2O_2$  was detected only after 45 days of oxygen deprivation.

Waterlogging-induced production of  $H_2O_2$  is also involved in the signaling and induction of various defense-related genes, leading to the synthesis of proteins/enzymes imparting hypoxia tolerance (Sairam et al., 2009). Excessive production of ROS can oxidize biological molecules, such as DNA, protein, and lipids, causing the malfunction of these molecules (Richter and Schweizer, 1997). Oxidative stress is an integral part of oxygen deprivation stress. Enhanced lipid peroxidation products have been observed in plants under low oxygen condition (Yan et al., 1996; Chirkova et al., 1998; Blokhina et al., 1999). The increased level of TBARS was observed at 4 and 6 days of waterlogging in pigeon pea plants over control plants, probably due to the activation of diphenyleneiodonium-sensitive NADPH oxidase (Kumutha et al., 2009). The injury of biological lipids by ROS, as indicated by MDA content, was clearly detected in the waterlogged barley plants, but with distinct difference between the Xiumai 3 (tolerant) and Gerdner (sensitive) genotypes, implying the possible difference in the capacity of their defense systems against ROS (Zhang et al., 2007). Thus, the sensitivity of plants to environment stress, including waterlogging, has been considered to be associated with antioxidative ability (Crawford, 1978; Foyer et al., 1994). Jamei et al. (2009) showed that the excessive accumulation of  $H_2O_2$ - and  $O_2^{\cdot-}$ -induced membrane damage and lipid peroxidation in leaves of *Zea mays* subjected to hypoxia was the result of the reduced activity of SOD.

When the activities of antioxidant enzymes were examined for the waterlogging tolerance of pigeon pea (*Cajanus cajan* L. Halls) genotypes ICP 301 (tolerant) and Pusa 207 (sensitive), it was observed that the activities of enzymes SOD, APX, GR, and CAT increased under waterlogging in both the cultivars and that, comparatively, greater antioxidant enzyme activities resulting in less oxidative stress were observed in the tolerant genotype ICP 301 compared to the sensitive genotype Pusa 207, suggesting that the greater activities of antioxidative enzymes represent one of the factors determining the higher tolerance of pigeon pea plants to flooding (Kumutha et al., 2009). Lin et al. (2008) observed that increased APX activity, increased levels of total GSH, oxidized, and total AsA at different days of flooding, confer flooding tolerance to the sweet potato plants (*Ipomoea batatas* L. Lam. "Tainung 57"). When eggplant genotypes EG117 and EG203, and tomato genotypes, L4422 and TNVEG6, were subjected to seven flooding treatments, the activity of APX in roots significantly increased during the period of continuous waterlogging (Lin et al., 2004). Slight increases in total AsA, reduced AsA, GSH, and total GSH contents in the roots were also observed throughout the entire waterlogging period. However, the activities of CAT, SOD, and GR, and the contents of AsA, GSSG, and  $\alpha$ -tocopherol in the roots were unaffected by waterlogging (Lin et al., 2004). Genotypes responded differently to oxidative injury according to the activity of their different antioxidative components. Following waterlogging treatments, APX activity in the eggplants was generally higher than in tomatoes. Limiting or less efficient APX in the tomatoes, led to the accumulation of  $H_2O_2$ . It was concluded that increased APX activity could provide increased tolerance to waterlogging in the plants (Lin et al., 2004).

Rice seedlings raised under water for 6 days showed reduced activities of SOD, APX, MDHAR, DHAR, GR, and CAT compared to seedlings raised in air for the same period of time (Ushimaru et al., 1992). AsA and GSH were present in submerged seedlings at nearly the same levels as those found in aerobically grown controls. When submerged, seedlings were exposed to air; the activities of the six antioxidative enzymes exceeded the levels in aerobically grown controls, during 24 h of adaptation to air. The level of AsA increased slightly, but the level of GSH showed a rapid increase, reaching seven times that in aerobically grown controls within 12 h of adaptation to air. Therefore, in this case, the development of antioxidative defense system was proposed to consist of two steps, namely, a rapid increase in the level of GSH and a subsequent slow increase in the activities of antioxidant enzymes (Ushimaru et al., 1992). The antioxidant systems of root and leaf cells behave differentially to changes in oxygen concentration. In leaves, low-mass antioxidants play the major role in ROS detoxification, while in roots, increased alternative oxidase capacity supports the antioxidant systems, possibly by preventing ROS formation (Skutnik and Rychter, 2009).

When the responses of antioxidant enzymes to the different depths of waterlogging in creeping bentgrass (*Agrostis stolonifera* L.) roots were examined, it was observed that SOD and APX were mainly involved in waterlogging-induced antioxidant responses, and that partial waterlogging could also significantly affect root antioxidant activities (Lin et al., 2004). The ability to maintain a balance between the formation and detoxification of ROS appears likely to contribute to the increased survival potential and the tolerance of the roots against oxidative stress (Lin et al., 2004).

#### 5.4.7 GASEOUS POLLUTANTS

The problem related to gaseous pollutants has increased during the recent years. Ozone, the most abundant air pollutant is detrimental to plants, because of its strong oxidizing potential. Ozone concentration and exposure time determine the chronic or acute toxicity and, consequently, the severity of injury at biochemical and physiological level. Ozone induces the formation of ROS in plants. Tropospheric ozone damages crop plants and forests by entering leaf mesophyll tissues through the stomata and rapidly generating ROS- $O_2^-$ ,  $\cdot OH$ ,  $H_2O_2$  at the cell perimeter (Pellinen et al., 1999; Pasqualini et al., 2002). Ozone that enters plants through the stomata is rapidly broken down into various ROS at the cell wall interface. Recently, however, it has been shown that ozone induces active ROS production. The ozone-induced accumulation of  $H_2O_2$  is observed initially on the plasma membrane and cell wall in birch (*Betula pendula*) (Pellinen et al., 1999). Experiments with inhibitors of possible sources for  $H_2O_2$  production in the cell wall suggested that both NADPH-dependent superoxide synthase and the cell wall POD are involved in such  $H_2O_2$  production. The  $H_2O_2$  production continued in the cytoplasm, mitochondria, and peroxisomes when the ozone exposure was over, but not in chloroplasts. The timing of mitochondrial  $H_2O_2$  accumulation coincided with the first symptoms of visible damage and, at the same time, the mitochondria showed disintegration of the matrix. These responses may not be directly connected with defense against oxidative stress, but may rather indicate changes in oxidative balance within the cells that affect mitochondrial metabolism and the homeostasis of the whole cell, possibly leading to the induction of programmed cell death (Pellinen et al., 1999). In sensitive plant species, even a few hours of exposure to this potent oxidant leads to severe oxidative stress that manifests the symptoms of visible cell death. Two mechanisms have been suggested for the injury brought about by ozone or ozone-induced ROS production: (1) modification of proteins (Rao et al., 1995), lipids (Calatayud and Barreno, 2001), and nucleic acids (Rousseaux et al., 1999), and (2) activation of programmed cell death pathway, similar to the pathogen-induced hypersensitive response (Overmyer et al., 2005). It has been postulated that ozone or ozone-induced ROS may locally cause necrotic cell death that, in turn, can trigger the PCD pathway in surrounding tissues. An acute exposure to 150 ppb ozone decreased stomatal conductance to 60%–70% of its initial value within 9–12 min in *Arabidopsis* plants (Kollist et al., 2007). The transient decrease was absent in the abscisic acid-insensitive mutant *abi2* defective in a class 2C protein phosphatase. This provides an *in vivo* confirmation that the early transient decrease

in stomatal conductance is not a result of physical damage by the ROS formed from ozone breakdown but reflects the biological action of ROS, transduced through a signaling cascade (Kollist et al., 2007). Highly significant interactions between ozone damage and levels of ROS, AsA, GSH, and lipid peroxidation were observed in *Medicago truncatula* accessions from various geographical regions. There were significant differences among the accessions for these traits before and after the end of ozone fumigation, suggesting that multiple physiological and biochemical mechanisms may govern ozone tolerance or sensitivity (Puckette et al., 2007). Acute ozone treatment (300 nL L<sup>-1</sup> for 6 h) led to a ROS burst in sensitive genotype Jemalong, 6 h postfumigation, whereas in resistant genotype JE154, increase in ROS levels was much reduced. Unique and shared transcriptional responses in an ozone-resistant and sensitive accession exemplify the complexity of oxidative signaling in plants (Puckette et al., 2007). It has been speculated that plants sensitive to acute ozone are impaired in the perception of the initial signals generated by the action of this oxidant. This, in turn, leads to a delayed transcriptional response in the ozone-sensitive plants. In resistant plants, the rapid and sustained activation of several signaling pathways enables the deployment of multiple mechanisms for minimizing the toxicity effect of this reactive molecule (Puckette et al., 2008).

In living organisms, ROS, directly or indirectly derived from ozone exposure, are scavenged by enzymatic and nonenzymatic antioxidant defensive mechanisms, overall deputed to preserve cell structures and macromolecules from the oxidative damage. These defenses are essentially those also involved in detoxifying the ROS inevitably produced by the metabolism of organisms living in oxygenic atmosphere (Iriti and Faoro, 2008). Studies on enzymatic and nonenzymatic antioxidants in two species belonging to a natural ecosystem, *Trifolium repens* L. (cv. Sonja) and *Trifolium pratense* L. (cv. Milvus) in response to an acute ozone dose, revealed that *T. repens* had higher constitutive levels of the defense molecules compared with the other species. Moreover, it proved to be more prone to activate the antioxidant systems in response to ozone, showing a lower degree of sensitivity to the pollutants (Scebba et al., 2003). Rao et al. (1996) observed that *A. thaliana* genotype Landsberg erecta was capable of metabolizing ozone-induced activated oxygen by invoking the enzymes of SOD/AsA–GSH cycle. Ozone exposure not only enhanced SOD, POD, GR, and APX activity but also modified the substrate affinity of both GR and APX (Rao et al., 1996). Ozone impacts on the yield and quality of crops is influenced by changing climatic conditions, increasing atmospheric CO<sub>2</sub>, and altered emission patterns (Fuhrer, 2009). Enhanced oxidative damage to proteins was observed in wheat plants (*Triticum aestivum* L. cv. Roblin) exposed to ozone under ambient CO<sub>2</sub> but not in plants exposed to ozone under high CO<sub>2</sub> (Rao et al., 1995). Ozone exposure initially enhanced the specific activities of SOD, POD, GR, and APX irrespective of growth in ambient or high CO<sub>2</sub>. However, the specific activities decreased in plants with prolonged exposure to ozone under ambient CO<sub>2</sub> but not in plants exposed to ozone under high CO<sub>2</sub>. Preferential changes in the isoform composition of SOD, POD, and APX was observed in plants grown under a combination of high CO<sub>2</sub> and ozone. A new isoform of GR was observed in plants grown under high CO<sub>2</sub> and ozone, which could be the reason for higher resistance of these plants to ozone-induced damage compared to plants exposed to ozone under ambient CO<sub>2</sub> (Rao et al., 1995). To study the relation between ozone sensitivity and leaf concentrations of antioxidants (AsA, total phenolics, and total antioxidant capacity), Severino et al. (2007) exposed ozone-sensitive (NC-S clone) and resistant plants (NC-R clone) of *Trifolium repens* and *Centaurea jacea* to moderate ozone concentrations in ambient air. NC-R clone showed the highest concentrations of antioxidants with 50%–70% more AsA than NC-S. NC-R had about five times more AsA in the young leaves and nine times more in the older leaves than *Centaurea*. In a fumigation experiment with acute ozone stress (100 nL L<sup>-1</sup>), the antioxidant levels changed profoundly. The ozone-injured leaves of NC-S had 6–8 times more total phenolics than uninjured leaves. Generally, older leaves had lower antioxidant concentrations and were more prone to ozone injury than younger leaves. Low AsA concentrations were closely related to the appearance of visible ozone injury than the other antioxidant parameters.

Sulfur dioxide (SO<sub>2</sub>) is a gaseous pollutant widely diffused in the world today. SO<sub>2</sub> penetrates in the leaves through the stomata. It dissolves in the aqueous medium surrounding the plant cells,

generating the toxic molecular species sulfite and bisulfite. The detoxification reaction of sulfite to sulfate, which takes place by reactions initiated by light, is mediated by the photosynthetic electron transport chain (Asada, 1980) and it leads to the formation of  $O_2^{\cdot-}$ ,  $\cdot OH$ ,  $H_2O_2$  (Asada, 1980). These highly oxidant molecular species, together with the toxic sulfite, can damage the lipids and proteins of cell membranes. The damage of leaves by  $SO_2$  in the presence of light has been attributed to the oxidative chain reaction of sulfite initiated by  $O_2^{\cdot-}$  produced as a result of the Mehler reaction in chloroplasts (Asada and Takahashi, 1987). Plants of two wheat (*Triticum aestivum* L.) cvs. namely "Mec" and "Chiarano," each with a different sensitivity to  $SO_2$ , when exposed to  $SO_2$ , revealed that different sensitivities to  $SO_2$  of the two cultivars were due to differential ability to maintain the elevated levels of AsA rather than increasing detoxifying enzyme activities (Ranieri et al., 1997). A significant increase in AsA, GSH, and their redox state was observed in plants exposed to high  $CO_2$  and  $SO_2$ , compared to that of plants exposed to solely  $SO_2$ . The absence of the negative effects of  $SO_2$  in the presence of high  $CO_2$  has been correlated to a high redox state of AsA and GSH (Rao and Dekok, 1994).

#### 5.4.8 UV-B RADIATIONS

The most damaging part of the UV spectrum reaching the earth's atmosphere is UV-B (290–320 nm). Increase in solar UV-B radiation reaching the earth's surface due to the depletion of the stratospheric ozone layer has become a major global concern (Blumthaler and Ambach, 1990; Xiong and Day, 2001). UV-B impairs several biochemical and physiological processes, including gene expression (Greenberg et al., 1989; Booij-James et al., 2000). UV-B radiation has a negative impact on plant cells, including enhanced generation of ROS, reduced photosynthesis, decreased protein synthesis, and impaired chloroplast functions (Strid et al., 1994; Booij-James et al., 2000; Han et al., 2009). UV-B causes oxidative stress through the excessive production of ROS  $O_2^{\cdot-}$ ,  $\cdot OH$ ,  $H_2O_2$  (Strid et al., 1994; Han et al., 2009), which, in turn, causes enhanced lipid and protein oxidation (Landry et al., 1995; Mittler, 2002; Babu et al., 2003; Frohnmeyer and Staiger, 2003; Yannarelli et al., 2006; Lu et al., 2009). The mechanisms of ROS generation by UV are not well understood (Green and Fluhr, 1995; Hideg et al., 2002). Rao et al. (1996) demonstrated that UV-B radiation enhances the activated oxygen species by increasing membrane-localized NADPH-oxidase activity and decreasing CAT activities (Rao et al., 1996). Plants must adapt to the deleterious effects of UV-B radiation because they are dependent on sunlight for photosynthesis and, therefore, cannot avoid exposure to UV-B radiation. Besides, antioxidative enzymatic scavengers for ROS such as SOD, POD, CAT, and APX, and nonenzymatic antioxidants like AsA and GSH, plants possess substances such as UV-B absorbing compounds and carotenoids to keep the balance between the production and removal of ROS (Costa et al., 2002; Han et al., 2009). In *Picea asperata* seedlings, enhanced UV-B (30%) induced the overproduction of ROS, leading to oxidative stress. UV-B increased the efficiency of antioxidant defense system consisting of UV-B absorbing compounds, carotenoids, and antioxidant enzymes SOD, APX, CAT, and POD (Han et al., 2009). UV-B exposure preferentially enhanced GPX, APX, and POD specific to coniferyl alcohol and modified the substrate affinity of APX in *A. thaliana*. New isoforms of PODs and APX were synthesized in flavonoid-deficient mutant transparent testa (*tt5*) of *A. thaliana* (Rao et al., 1996). Leaves from bitter melon (*Momordica charantia* L.) subjected to UV-B at three different stages of plant growth: preflowering, flowering, and postflowering revealed that the activities of SOD, CAT, POD, polyphenol oxidase, GR, and the concentrations of AsA,  $H_2O_2$ , and TBARS were elevated under UV-B exposure at all growth stages with the exception of  $H_2O_2$  concentration at the postflowering stage. It is suggested that *M. charantia* exhibits a protection mechanism against oxidative damage by maintaining a highly induced antioxidant system under UV-B stresses (Agarwal and Shaheen, 2007). Numerous studies have shown that large differences in UV-B sensitivity exist among plant species and even between cvs. of the same species (Teramura and Murali, 1986; Barnes et al., 1993). Santos et al. (1999) observed the influence of UV-B radiation on the activity of SOD and the number and amount of isoforms in the leaves of

C<sub>3</sub> plants, potato and wheat, and C<sub>4</sub> plants, maize and sorghum. The total specific activity of SOD increased significantly in wheat, maize, and potato, whereas a decline was induced in sorghum. Native gels revealed that UV-B caused preferential changes of the SOD isoforms in all plants. The rise in SOD activity in maize, potato, and wheat was correlated with the UV-B tolerance of these crops, and the sensitivity of sorghum to UV-B was associated with the decrease in SOD activity.

Gao and Zhang (2008) studied the response of an AsA-deficient *Arabidopsis thaliana* mutant *vtc1* to short-term increased UV-B exposure. After UV-B supplementation, *vtc1* mutants showed increase in H<sub>2</sub>O<sub>2</sub> content and the production of TBARS and a decrease in chlorophyll content and chlorophyll fluorescence parameters. The reduced ratio of GSH/total GSH and the increased ratio of DHA/total AsA were observed in the *vtc1* mutants, compared to the wild-type plants. In addition, the enzymes responsible for ROS scavenging, such as SOD, CAT, and APX and enzymes responsible for the regeneration of AsA and GSH (including MDHAR, DHAR, and GR) had insufficient activity in the *vtc1* mutants, compared to the wild-type plants. These results suggest that the AsA-deficient mutant *vtc1* is more sensitive to supplementary UV-B treatment than wild-type plants and AsA can be considered as an important antioxidant for UV-B radiation (Gao and Zhang, 2008).

## 5.5 PRODUCTION OF ABIOTIC STRESS-TOLERANT TRANSGENIC CROP PLANTS USING COMPONENTS OF ANTIOXIDATIVE DEFENSE SYSTEM

Oxidative stress is a key factor involved in the expression of abiotic stress-induced damages in crop plants. Maintaining redox balance is one of the crucial requirements for cells to endure abiotic stresses. Tolerance to several abiotic stresses has been correlated well with the enhanced level of components of antioxidant defense mechanism. Transgenic plants offer novel possibilities to achieve complete understanding of the roles of different enzymes and biomolecules involved in protection against the stresses of many types. Genetic engineering approaches have gained considerable grounds in terms of improving the traits of many crops within the shortest possible time period. Transgenic plants overexpressing enzymatic and nonenzymatic components of antioxidant defense system, singly or in combination, can be successfully used as attractive targets to produce abiotic stress-tolerant plants using biotechnological approaches.

The enhancement of the capacity of antioxidative defense system using gene transfer technology has shown to enhance the tolerance of crop plants to abiotic stresses, with improved performance and productivity under these stresses. Table 5.2 provides an overview of abiotic stress-tolerant plants produced by overexpressing the different enzymatic components of antioxidative defense mechanism. SOD serves as the first enzyme in the chain of enzymatic components of antioxidative defense system. Increased tolerance to some of the environmental stresses has been achieved by overexpressing SOD in target plants (Matters and Scandalios, 1986; Slooten et al., 1995a). Tolerance to drought (Badawi et al., 2004; Wang et al., 2005a), salinity (Liu et al., 2003; Prashanth et al., 2008; Zhang et al., 2008), low-temperature stress (Gupta et al., 1993; McKersie et al., 1993; Lee et al., 2009), and ozone (Van Camp et al., 1994) has been achieved by overexpressing SOD. The overexpression of wheat *TaSOD1.1* and *TaSOD1.2* genes increased SOD activities and decreased MDA content, resulting in less overoxidation of the cellular membrane system and the enhancement of physiological functions, with improved low-temperature stress tolerance and NaCl tolerance in transgenic tobacco plants (Zhang et al., 2008, 2009). Under salt stress, the upregulation of exotic target genes was also observed in transgenic plants at the transcriptional level, which could further enhance the salt-tolerant capacity of these plants (Zhang et al., 2008). Halophytic plants like mangroves have been reported to have a high level of SOD activity, which plays a major role in defending the mangrove species against severe abiotic stresses. *Sod1*, a cDNA encoding a cytosolic Cu/Zn-SOD from the mangrove plant *Avicennia marina* was expressed in rice. The transgenic plants withstood salinity stress of 150 mM of NaCl for a period of 8 days while the untransformed control plants wilted at the end of the stress treatment in hydroponics. The transgenic plants also revealed better tolerance to drought stress in comparison to untransformed control plants (Prashanth et al., 2008).

**TABLE 5.2**

|                     | Salinity              | <i>Arabidopsis thaliana</i>    | Qi et al. (2004)            |

A chimeric gene consisting of the coding sequence for cytosolic Cu/Zn-SODs from *Oryza sativa* fused to the chloroplast transit sequence from *Arabidopsis thaliana* GR was used for generating transgenic tobacco plants. The first generation of the transgenic lines showed enhanced tolerance to salt and water stresses over the wild type, suggesting that the overexpressed Cu/Zn-SOD enhances the chloroplast antioxidant system (Badawi et al., 2004).

Transgenic *Arabidopsis* plants overexpressing Mn-SOD showed enhanced tolerance to salt stress (Wang et al., 2004). When Mn-SOD from *Nicotiana plumbaginifolia* was targeted to tobacco mitochondria, only a minor effect on ozone tolerance was observed. However, the overproduction of SOD in the chloroplasts resulted in a 3–4 fold reduction of visible ozone injury in transgenic tobacco plants (Van Camp et al., 1994). The overexpression of Fe-SOD increases  $O_2^{\cdot-}$ -scavenging capacity and thereby improves the oxidative stress tolerance of plants. Transgenic alfalfa plants transformed with *Arabidopsis* Fe-SOD with a chloroplast transit peptide showed a novel Fe-SOD in native PAGE. As no detectable difference in the pattern of primary freezing injury, as shown by vital staining, or additional accumulation of carbohydrates in field-acclimated roots of the transgenic alfalfa plants could be observed, it was suggested that Fe-SOD overexpression reduced secondary injury symptoms and thereby enhanced recovery from stresses experienced during winter (McKersie et al., 2000).

Attempts have been made to improve the stress tolerance of many crop plants by manipulating CAT genes (Mohamed et al., 2003; Nagamiya et al., 2007; Moriwaki et al., 2008; Guan et al., 2009). Salinity stress is a major limiting factor in the productivity of cereals. In an attempt to improve salt tolerance of rice, a CAT gene of *Escherichia coli*, *katE* was introduced into japonica rice cv. Nipponbare and indica rice cv., BR5. The resultant transgenic rice plants constitutively expressing *katE* were more tolerant to NaCl than wild-type plants (Nagamiya et al., 2007; Moriwaki et al., 2008). When bacterial CAT gene was overexpressed in tomato chloroplasts, the transgenic plants had increased tolerance to photo-oxidative stress imposed by drought stress or chilling stress (Mohamed et al., 2003). CAT has also been used in preventing the plant from Cd-induced oxidative stress caused by ROS. When a CAT gene from *Brassica juncea* was introduced into tobacco, wild-type plants became chlorotic and almost dead while transgenic tobacco plants still remained green and phenotypically normal under 100 mM Cd treatment (Guan et al., 2009).

APX plays an important role in scavenging ROS by degrading  $H_2O_2$  in plants. The use of APX genes for plant transformation has led to the development of transgenic plants with enhanced tolerance to oxidative stress (Slooten et al., 1995b; Wang et al., 2005b; Duan et al., 2006; Xu et al., 2008a,b). Overexpressing a cytosolic APX from *Arabidopsis thaliana* in the chloroplasts of *Nicotiana tabacum* cv. SR1 resulted in a significantly enhanced  $H_2O_2$  scavenging capacity (Slooten et al., 1995b). The different isoforms of APX in cytosol have different functional roles in rice. Transgenic lines overexpressing OsAPXb showed higher salt tolerance than OsAPXa transgenic *Arabidopsis* lines. Enhanced active oxygen scavenging system was suggested to protect plants from salt stress by equilibrating  $H_2O_2$  metabolism in these lines. The overproduction of OsAPXb enhanced and maintained the higher level of APX activity than OsAPXa in transgenic *Arabidopsis* during treatment with different concentrations of NaCl. Findings suggest that the rice cytosolic OsAPXb gene has a more functional role than OsAPXa in the improvement of salt tolerance in transgenic plants (Lu et al., 2007). Thylakoid-bound APX and peroxisomal type APX (pAPX) also play an important role in protection against various abiotic stress-induced oxidative stresses (Xu et al., 2008a,b; Sun et al., 2009). When thylakoid-bound APX gene (*LetAPX*) from tomato was overexpressed in tobacco, improved salt tolerance was observed in transgenic plants (Sun et al., 2009). Transgenic *Arabidopsis thaliana* plants carrying a pAPX gene (*HvAPXI*) from barley were found to be more tolerant to salt stress than the wild type. The salt tolerance in transgenic plants was not due to the maintenance and re-establishment of cellular ion homeostasis but by the reduction of oxidative stress injury (Xu et al., 2008a). Transgenic rice plants overexpressing *HvAPXI* under excessive Cd were significantly more tolerant to Cd stress and accumulated more Cd compared to the wild-type plants (Duan et al., 2006). *HvAPXI* also plays important roles in protection against excessive Zn-induced oxidative stress and appears to be a novel candidate gene for developing high-biomass Zn-tolerant plants for phytoremediation of Zn-polluted environments (Xu et al., 2008b). The mechanism of Zn tolerance in transgenic plants was suggested to be due to reduced oxidative stress damage.

The enzyme MDHAR is crucial for the regeneration of AsA and essential for maintaining a reduced pool of AsA. The overexpression of *MDHAR* has been shown to minimize the deleterious effects of environmental stresses (Eltayeb et al., 2007). Transgenic tobacco plants overexpressing *Arabidopsis thaliana MDHAR* gene (*AtMDAR1*) in the cytosol exhibited up to 2.1-fold higher MDAR1 activity and 2.2-fold higher level of reduced AsA compared to nontransformed control plants. The transgenic plants showed enhanced stress tolerance in terms of significantly higher net photosynthesis rates under ozone, salt, and PEG stresses and greater PSII effective quantum yield under ozone and salt stresses. Furthermore, these transgenic plants exhibited significantly lower  $H_2O_2$  level when tested under salt stress (Eltayeb et al., 2007). These results demonstrate that an overexpressed level of *MDAR* properly confers enhanced tolerance against ozone, salt, and PEG stress (Eltayeb et al., 2007).

The enzyme DHAR is assumed to be critical for AsA recycling. The manipulation of DHAR expression is important for the genetic engineering of stress-tolerant plants (Kwon et al., 2003; Ushimaru et al., 2006; Amako and Ushimaru, 2009). The expression of rice DHAR in transgenic

*Arabidopsis thaliana* enhanced resistance to salt stress (Ushimaru et al., 2006). Similarly, enhanced tolerance to NaCl and low temperature was observed when a human DHAR was overexpressed in tobacco plants. Transgenic plants showed higher DHAR and GR activities than nontransgenic plants and the ratio of AsA/DHA increased from 0.21 to 0.48, even though total AsA content was not significantly changed. When tobacco leaf discs were subjected to oxidative stress, reduction in membrane damage relative to nontransgenic plants was observed. Furthermore, transgenic plants showed enhanced tolerance to low temperature and NaCl compared to nontransgenic plants (Kwon et al., 2003). Glutathione peroxidase reduces  $H_2O_2$  to  $H_2O$  by oxidizing GSH. Transgenic tobacco seedlings overexpressing glutathione S-transferase with glutathione peroxidase activity resulted in enhanced growth under a variety of stressful conditions (Roxas et al., 2000). Similarly, the overexpression of glutathione S-transferase gene of *Suaeda salsa* enhanced the salt tolerance of transgenic *Arabidopsis* plants (Qi et al., 2004). Increased GSH-dependent peroxide scavenging and alterations in GSH and AsA metabolism was suggested to reduce abiotic stress-induced oxidative damage in glutathione S-transferase overexpressed transgenic plants (Roxas et al., 2000; Qi et al., 2004). Glutathione peroxidase-like protein overexpressed either in the cytosol or in chloroplasts of tobacco plants increased tolerance to oxidative stress caused by various stressful conditions by removing unsaturated fatty acid hydroperoxides generated in cellular membranes (Yoshimura et al., 2004).

Flavonoids are a class of plant secondary metabolites. Increased flavonoids content has been used to generate potato tubers with modified antioxidant capacities. The single-gene overexpression or the simultaneous expression of genes encoding chalcone synthase (CHS), chalcone isomerase (CHI), and dihydroflavonol reductase (DFR) resulted in a significant increase of measured phenolic acids and level of anthocyanins accompanied by decreases in starch and glucose levels in transgenic plants. The flavonoids-enriched plants showed improved antioxidant capacity, however the participation of other compounds (which are not yet recognized) was also suggested in rendering antioxidant potential to the plants (Lukaszewicz et al., 2004). In plants, the xanthophyll cycle (the reversible interconversion of two carotenoids, violaxanthin, and zeaxanthin) is a promising target for genetic engineering to enhance stress tolerance. In *Arabidopsis thaliana*, the overexpression of the *chyB* gene that encodes  $\beta$ -carotene hydroxylase, an enzyme in the zeaxanthin biosynthetic pathway, causes a specific twofold increase in the size of the xanthophyll cycle pool. The plants are more tolerant to conditions of high light and high temperature, as shown by reduced leaf necrosis, reduced production of the stress indicator anthocyanin, and reduced lipid peroxidation. Stress protection was suggested to be due to the function of zeaxanthin in preventing the oxidative damage of membranes (Davison et al., 2002). In view of the antioxidant properties of  $\alpha$ -tocopherol, it is suggested that the overexpression of  $\alpha$ -tocopherol can increase the tolerance of plants to oxidative stress caused by abiotic stresses (Liu et al., 2008). Tocopherol cyclase (VTE1, encoded by *VTE1* gene) catalyzes the penultimate step of tocopherol synthesis. Transgenic tobacco plants overexpressing VTE1 from *Arabidopsis* showed decreased lipid peroxidation, electrolyte leakage, and  $H_2O_2$  content, compared to the wild type when exposed to drought conditions (Liu et al., 2008).

Though it is possible to confer a certain degree of tolerance to a particular stress by overexpressing a single component of antioxidant defense system, only limited improvement in stress tolerance has been observed in these plants (Lee et al., 2009). As ROS detoxification system is very complex, overexpressing one enzyme may or may not change the capacity of the whole pathway. Therefore, increases in one component may not result in an overall increase in protection (Lee et al., 2009). For example, Rubio et al. (2002) found no improvement to oxidative or environmental stress tolerance in transgenic alfalfa overexpressing SOD. Similarly, rice plants overexpressing *SodCc1*, encoding Cu/Zn-SOD showed no enhanced tolerance to oxidative stress. Further, wilting assay also demonstrated no improvement in tolerance to either cold or drought (Lee et al., 2009). The expression of combinations of antioxidant enzymes in transgenic plants has been shown to have synergistic effects on stress tolerance (Tseng et al., 2008). Chinese cabbage overexpressing both SOD and CAT in cytosol shows considerable tolerance to  $SO_2$  damage (Tseng et al., 2008). Transgenic plants with an enhanced tolerance to multiple environmental stresses have been developed by overexpressing

the genes of both SOD and APX in the chloroplasts (Kwon et al., 2002; Lee et al., 2007; Lim et al., 2007; Kwak et al., 2009). Lee et al. (2007) showed that the simultaneous expression of multiple antioxidant enzymes, such as Cu/Zn-SOD, APX, and DHAR, in chloroplasts is more effective than single or double expression for developing transgenic plants with enhanced tolerance to multiple environmental stresses.

## 5.6 CONCLUSIONS AND FUTURE PROSPECTS

One of the inevitable consequences of abiotic stresses like drought, salinity, heat, chilling, heavy metal, anaerobiosis, gaseous pollutants, and UV-B radiation involves the production of ROS in different cellular compartments, such as chloroplasts, peroxisomes, and mitochondria. ROS play two divergent roles in plants: in low concentrations, they act as signaling molecules for the activation of defense responses under stresses, whereas in high concentrations, they cause exacerbating damage to cellular components. If prolonged over a certain extent, abiotic stresses, through overproduction of ROS, would result in oxidative damage to lipids, proteins, and nucleic acids, in turn causing severe damage to cell viability. The enhanced production of ROS is, however, kept under tight control by versatile and cooperative ROS-scavenging antioxidant mechanisms that modulate intracellular ROS concentration. These mechanisms can be conveniently divided in two groups, viz. nonenzymic antioxidants such as GSH, AsA, tocopherols, carotenoids, etc., and the enzymic antioxidants like CAT, POX, SOD, as well as enzymes of AsA–GSH cycle such as APX, MDHAR, DHAR, and GR. Antioxidant responses of plants not only depend on the species-inherent strategy but also on the tissue, duration, and severity of the stress period. Molecular and cellular knowledge associated with abiotic stress induced various damages, and metabolic alterations are necessary to improve abiotic stress tolerance in plants. Naturally, abiotic stress-tolerant plants provide helpful tools for such research. Enhancements in the expression of components of antioxidant defense system involved in ROS-scavenging show significant improvements in metabolic status of plants, and this strategy has been used to develop crop plants with enhanced stress tolerance. The study of the genetically transformed plants has allowed us to understand the roles of individual enzymes in metabolic regulations. However, attempts to increase abiotic stress tolerance by overexpressing one of the components of antioxidant defense system have not always been successful because it may not change the capacity of the pathway as a whole. Further, it can disturb the balanced interaction among the components. The expressions of the combination of antioxidant components have shown synergistic effects on stress tolerance and have been used frequently to produce transgenic plants with enhanced tolerance to abiotic stresses. Various abiotic stressful conditions of the environment severely limit agricultural productivity throughout the world. Therefore, future work employing biotechnological approaches is essential to produce crop plants with in-built capacity of enhanced levels of multiple abiotic stress tolerance by constitutively expressing high levels of antioxidants, for cultivation in stress-prone environments.

Ever since the introduction of molecular oxygen ( $O_2$ ) into our atmosphere by  $O_2$ -evolving photosynthetic organisms 2.7 billion years ago, reactive oxygen species (ROS) have been the unwelcome companions of aerobic life. In contrast to  $O_2$ , these partially reduced or activated derivatives of oxygen [singlet oxygen ( $^1O_2$ ), superoxide anion ( $O_2^-$ ), hydrogen peroxide ( $H_2O_2$ ) and hydroxyl radical ( $HO\cdot$ )] are highly reactive and toxic, and can lead to the oxidative destruction of cells. Consequently, the evolution of all aerobic organisms has been dependent on the development of efficient ROS-scavenging mechanisms. In recent years, a new role for ROS has been identified: the control and regulation of biological processes, such as growth, cell cycle, programmed cell death, hormone signaling, biotic and abiotic stress responses, and development. These studies extend our understanding of ROS and suggest a dual role for ROS in plant biology as both toxic byproducts of aerobic metabolism and key regulators of growth, development, and defense pathways. How this dual role is controlled in plants is largely unknown. However, it is clear that the steady-state level of ROS in cells needs to be tightly regulated. In *Arabidopsis*, a network of more than 150 genes is involved in managing the level of ROS. This network is highly dynamic and redundant, and encodes ROS-scavenging and ROS-producing proteins. Recent studies have unraveled some of the key players in the network, but many questions related to its mode of regulation, its protective roles and its modulation of signaling networks that control growth, development and stress response remain unanswered. The hunt for ROS receptors in plants is still open. It has been suggested that plant cells sense ROS via at least three different mechanisms: (1) unidentified receptor proteins; (2) redox-sensitive transcription factors, such as NPR1 or Heat Shock Factors; and (3) direct inhibition of phosphatases by ROS. Continued genomics, proteomics and metabolomics efforts and other emerging technologies are likely to provide a more detailed picture of the networks involved in different ROS-related plant processes. Because ROS play a regulatory role

in plants response and adaptation to both biotic and abiotic stress situations, new insights into the ROS gene network might also allow the identification of genes that can ultimately be exploited to modulate ROS-related plant processes that lead to the generation of better performing crop plants. (by Frank Van Breusegem and Ron Mittle)

6.1 INTRODUCTION

Plants are frequently exposed to a plethora of unfavorable or even adverse conditions, called abiotic stresses, which lead to a series of morphological, physiological, biochemical, and molecular changes that prevent plants from reaching their full genetic potential, and hence limit the crop productivity. Abiotic stress is the principal cause of crop failure worldwide, dipping average yields for most major crops by more than 50% [1]. A common consequence of abiotic stresses is that they result, at some stage of stress exposure, in an increased production of ROS and subsequent oxidative stress. To maintain growth and productivity, plants must adapt themselves to stress conditions and set up specific protective mechanisms, including the protective mechanisms against oxidative stress. The chief aim of this chapter is to make a survey of protection by means of antioxidant systems against oxidative stress in plants during the action of various abiotic stresses.

6.2 REACTIVE OXYGEN SPECIES

Plants, being aerobic organisms, utilize molecular dioxygen (O<sub>2</sub>) as a terminal electron acceptor. The reduction of O<sub>2</sub> to H<sub>2</sub>O provides the energy that allows the impressive complexity of higher organisms on one hand, but on the other hand, its incomplete reduction produces ROS [2].

As oxidative stress together with ROS is elaborated in the chapter “Oxidative Stress in Plants: Production, Metabolism, and Biological Roles of Reactive Oxygen Species” by Tsanko Gechev and Ivan Minkov, Bulgaria, we will confine only to the compendium of the most important plant antioxidants together with their strategies in Table 6.1.

**TABLE 6.1**  
**Compendium of the Most Important Enzymatic and Nonenzymatic Antioxidants**  
**in Plants with Their Abbreviations Used in the Text**

| Antioxidant                            | Strategy                                                                                                                  |
|----------------------------------------|---------------------------------------------------------------------------------------------------------------------------|
| Superoxide dismutase (SOD)             | $2O_2^{\cdot-} + 2H^+ \Rightarrow O_2 + H_2O_2$                                                                           |
| Ascorbate peroxidase (APX)             | $H_2O_2 + 2Asc \Rightarrow 2H_2O + 2MDHA$                                                                                 |
| Monodehydroascorbate reductase (MDHAR) | $2MDHA + NAD(P)H + H^+ \Rightarrow 2Asc + NAD(P)^+$                                                                       |
| Dehydroascorbate reductase (DHAR)      | $2DHA + 2GSH \Rightarrow 2Asc + GSSG$                                                                                     |
| Glutathione reductase (GR)             | $GSSG + NAD(P)H + H^+ \Rightarrow 2GSH + NAD(P)^+$                                                                        |
| Catalase (CAT)                         | $2H_2O_2 \Rightarrow 2H_2O + O_2$                                                                                         |
| Glutathione peroxidase (GPX)           | $H_2O_2 + 2GSH \Rightarrow 2H_2O + GSSG$                                                                                  |
| Glutathione (GSH)                      | $H_2O_2 + 2GSH \Rightarrow 2H_2O + GSSG$<br>$GSH + OH^{\cdot} \Rightarrow H_2O + GS^{\cdot}$                              |
| Ascorbate (Asc)                        | $2Asc + H_2O_2 \Rightarrow 2H_2O + 2DHA$                                                                                  |
| β-carotene (β-car)                     | $\beta-car + ROO^{\cdot} \Rightarrow \beta-car^{\cdot} + ROOH$<br>$^3Chl^* + \beta-car \Rightarrow ^1Chl + ^3\beta-car^*$ |
| α-Tocopherol (α-toc)                   | $\alpha-toc + LOO^{\cdot} \Rightarrow \alpha-toc^{\cdot} + LOOH$                                                          |
| Xanthophyll cycle                      | Heat dissipation of excess energy                                                                                         |
| Flavonoids (Fl)                        | $Fl-OH + R^{\cdot} \Rightarrow Fl-O^{\cdot} + RH$                                                                         |
| Lycopene (Lyc)                         | $Lyc + O_2^{\cdot-} \Rightarrow Lyc^{\cdot-} + O_2$                                                                       |

### 6.3 DROUGHT STRESS

During drought stress, stomata are closed in order to limit water loss. In consequence, the CO<sub>2</sub> concentration is limited in the leaf mesophyll tissue. For example, the decrease of water potential to -3MPa and the relative water content to 42% caused a reduction of the maximum diurnal CO<sub>2</sub> assimilation rate by 80% in rosemary (*Rosmarinus officinalis* L.) [3]. The decrease of CO<sub>2</sub> results in an accumulation of NADPH (Photosystem I). The availability of NADP<sup>+</sup> (nicotinamide adenine dinucleotide phosphate), an electron acceptor for PSI (nicotinamide adenine dinucleotide phosphate, reduced form), is scarce. Under these conditions, O<sub>2</sub> acts as an alternate acceptor of electrons, resulting in the formation of O<sub>2</sub><sup>-</sup> [4]. Oxidative damage has been linked as the cause of plant injuries experienced during drought [5–7].

The changes in antioxidant enzyme activities depend on both severity and the duration of water shortage. GR (glutathione reductase) activity in wheat leaves was higher in drought stress than in irrigated plants [8]. On the other hand, in pea plants with a leaf water potential of about -1.3 MPa, CAT (catalase), DHAR (dehydroascorbate reductase), and GR activities decreased by 72%–85%, but APX (ascorbate peroxidase) and MDHAR (monodehydroascorbate reductase) decreased only by 15% [9]. In tobacco leaves, the CAT activity decreased, whereas the activities of APX, GR, and SOD (superoxide dismutase) were not affected significantly by water withdrawal. In the roots of the same plants, the responses were more significant: the activity of CAT, though very low, decreased, but GR and APX elevated in drought conditions [10].

Transient increases in SOD, APX, and GR activities occurred at 6 and 12 days of drought, respectively in both fescue (*Festuca arundinacea* L.) and Kentucky bluegrass (*Poa pratensis* L.); however, the activities of all three enzymes decreased with extended periods of drought [11]. For example, in *Vigna* seedlings, CAT activity and ascorbate content decreased with increasing water stress (-0.5 to -1.5 MPa) [12].

In many grass species, a rise in the total glutathione pool and a depletion of ascorbate was observed during drought stress [13]. The concentration of  $\alpha$ -tocopherol increased 15-fold and that of carotenoids by approximately 26% in water-stressed rosemary (*Rosmarinus officinalis* L.) [3]. Similarly, in sage (*Salvia officinalis* L.) and lemon balm (*Melissa officinalis* L.), significant increases in  $\alpha$ -tocopherol occurred, as well as the ascorbate level in chloroplasts increased [3]. In *Phyllyrea angustifolia* L., the amounts of  $\alpha$ -tocopherol increased up to fourfold and those of zeaxanthin, a pigment of the protective xanthophyll cycle, increased up to threefold. While  $\alpha$ -tocopherol increased further in severe drought, zeaxanthin and  $\beta$ -carotene decreased; during recovery, the  $\beta$ -carotene level increased slowly and the  $\alpha$ -tocopherol level decreased sharply [14].

### 6.4 WATERLOGGING

During waterlogging or submergence by excessive water, plants are exposed to a reduction in oxygen supply because of the slow diffusion rate of oxygen in water and its limited solubility [15]. Oxygen deprivation stress in plant cells is distinguished by three physiologically different states: transient hypoxia, anoxia, and, eventually, reoxygenation.

Hypoxic tissues exhibit enhanced mitochondria-dependent superoxide formation via xanthine oxidase, lipoyxygenase action on membrane lipids, and finally lipolytic acylhydrolase-catalyzed liberation of free fatty acids, which underpins a burst in lipid peroxidation or return to normoxia. Anaerobic tissues have a very high redox potential and the soil environment surrounding the roots contains highly reduced forms of metal ions, such as Fe<sup>2+</sup>, which can readily reduce atmospheric oxygen to a superoxide. Therefore, in the interim between the return to high oxygen partial pressures and the reactivation of the mitochondrial electron transport system, conditions are ideal for the activation of oxygen [16]. Hydrogen peroxide accumulation under hypoxic conditions has been shown in the roots and leaves of barley [17,18] and in wheat roots [19]. The presence of H<sub>2</sub>O<sub>2</sub> in the apoplast and in association with the plasma membrane has been visualized by transmission electron

microscopy under hypoxic conditions in four plant species [20]. In these experiments,  $H_2O_2$  was probably of enzymatic origin, considering the low oxygen concentration in the system and the positive effects of the various inhibitors of  $H_2O_2$ -producing enzymes. Indirect evidence of ROS formation (i.e., lipid peroxidation products) under low oxygen has been detected [21–25].

It was observed in a study with soybean roots that a short anoxic stress (1–2 h) increased the potential for superoxide production [26]. With longer durations of anoxia (3–5 h), the roots developed an increased ability to cope with oxygen-free radicals, and therefore exhibited less postanoxic injury. The increase in SOD activity has been reported in rhizomes of flooded *Iris pseudacorus* [27]. An increase in the total SOD activity has also been detected in wheat roots under anoxia but not under hypoxia. The degree of increase positively correlated with the duration of anoxia [19]. The induction of SOD activity by 40%–60% has been shown under hypoxia both in the roots and leaves of barley [17,18]. Short-term flooding led to an increase in the activities of GR, APX, CAT, and SOD in maize leaves, while under prolonged flooding, inhibition of these enzymes occurred [23]. In submerged seedlings (i.e., under hypoxic conditions), the activities of antioxidant enzymes were lower compared with air-germinated controls. On the other hand, the induction of enzymes involved in the ascorbate-dependent antioxidant system (APX, MDHAR, and DHAR) has been shown for anaerobically germinated rice seedlings after transfer to air [28]. Acclimation to anoxia has been shown to be dependent, at least partly, on peroxidases, which have been up-regulated by anoxic stress [29]. In rice seedlings, SOD activities responded nonsignificantly to submergence, while CAT activity increased upon the readmission of oxygen [30]. Investigations involving 11 species differing in their tolerance to anoxia have revealed an increase in MDHAR and/or DHAR in the anoxia-tolerant plants after several days of anoxic treatment. On the contrary, the activities were very low or without any changes in the sensitive plants [31]. A slight decrease in MDHAR, DHAR, and GR activities occurred in wheat seedlings under hypoxia, while anoxia caused a significant increase in the reduced ascorbate and glutathione [32].

The imposition of anoxia and subsequent reoxygenation caused a decrease both in the content of ascorbate and in its reduction state in the roots of cereals and the rhizomes of *Iris* spp. [33]. During long-term anoxic stress, tocopherol contents in the rhizomes of two iris species—highly anoxia-tolerant *Iris pseudacorus* and anoxia-sensitive *I. germanica*—have been compared. Tocopherols ( $\alpha$ - and  $\beta$ -) were identified in both iris species,  $\beta$ -tocopherol being the predominant tocopherol isomer, especially in rhizomes of *I. germanica*, which also possessed a markedly higher total tocopherol content than *I. pseudacorus*. Anoxia caused a decrease in the contents of tocopherol isomers in both iris species [33].

## 6.5 HIGH TEMPERATURE

In nature, plants are subjected to changes of temperature, both during the shift in season and, more abruptly, over the course of individual days. The temperature of an individual plant cell can change much more suddenly and rapidly than other factors causing stress, for example, water or salt levels [34].

The leaf copes with increasing temperature by opening stomata; the transpiration flow cools down the tissue [35]. However, when the temperature reaches high values, stomata close. The characteristic response to high temperature is the heat shock, characterized by the rapid induction of heat shock proteins (HSPs) that primarily function as molecular chaperones to ensure the correct function of many cellular proteins under conditions of elevated temperature [36]. HSP 70 was identified as a sensor of leaf temperature [37].

The photochemical efficiency of PSII decreases at elevated temperatures, indicating increased stress [38,39]. An intimate relationship appears to exist between oxidative stress and the heat shock response [40–42]. For example, tobacco seedlings showed a significant increase in  $H_2O_2$  after exposure to 40°C for 1 h [43]. Heat stress was shown to cause impairments in mitochondrial functions that resulted in the induction of oxidative damage [34,44]. Heat shock leading to a

programmed cell death in plants was shown to be associated with an enhanced production of ROS and the activation of the oxidative burst [36,45].

The steady-state transcript and protein level of many ROS-scavenging enzymes were found to be elevated by heat stress [36,45–49]. SOD activity increased up to ninefold in the heat-tolerant tomato cultivars but decreased in the heat-sensitive cultivar, whereas CAT and APX activities increased significantly in all cultivars [46]. In rice seedlings, the level of APX activity was higher in heated seedlings, whereas CAT activity was decreased. There was no significant difference in SOD activity between heated and unheated seedlings [36,47]. Both transgenic apple and tomato plants overexpressing cytosolic APX had improved resistance to heat stress [50,51].

## 6.6 LOW TEMPERATURE

Suboptimal growth temperatures provoke oxidative stress in plants. The amount of  $H_2O_2$  detected in leaves increases as the growth temperature declines [52–56]. The damage caused to mature and developing leaves by low-temperature stress manifests primarily in the chloroplasts, leading to the inhibition of photosynthesis and premature senescence [57–59]. Studies on the relationships between  $CO_2$  assimilation, photosynthetic electron transport, and antioxidant enzyme activities in field-grown maize suggested that the donation of electrons to oxygen by the photosynthetic electron transport chain was increased by plant growth at low temperatures [60]. However, the  $H_2O_2$  content in maize leaves was increased by growth at suboptimal temperatures, but was independent of irradiance [61,62]. This suggests that photosynthesis is not directly responsible for the low-temperature-induced increase in the foliar  $H_2O_2$  level [62].

There is evidence that the chilling tolerance of plants is correlated with increasing amounts of antioxidants and increasing activity of free-radical-scavenging enzymes. Exposure to low temperatures caused an increase in CAT and GR activities [63,64]. Similarly, high APX, MDHAR, DHAR, GR, and SOD activities and enhancement of the ascorbate and  $\alpha$ -tocopherol pools were observed in field-grown maize during periods when the plants were exposed to chilling [60]. Decreased CAT, APX, and MDHAR activities were found to be associated with chilling sensitivity during the early stages of development of four inbred lines of *Zea mays* [56,65,66]. While the activities of GR, APX, and SOD were markedly increased due to chilling, the activity of CAT changed to a lesser extent and was dependent on the maize genotype analyzed [67]. The response of antioxidant enzymes depended on the duration of chilling stress. GR activity increased with the increasing length of the cold period in maize, while SOD activity changes depended also on the maize genotype [68].

Higher GR activities and higher ascorbate level were found in leaves of the chilling-tolerant *Zea diploperennis* than in the chilling-sensitive *Zea mays* [69]. A chilling-tolerant maize genotype has been shown to contain higher amounts of both  $\alpha$ -tocopherol and glutathione and higher GR activity than a chilling-sensitive maize genotype [70]. Chilling-induced enhancement of the glutathione pool and constitutively higher GR activities were found to contribute to the chilling tolerance in *Zea mays* [71].

It is known that ascorbate regenerates tocopherols from their radical forms [72]. However, the artificially increased ascorbate content in maize leaves did not improve the preservation of endogenous tocopherol during high light and chilling stress [73].

## 6.7 EXPOSURE TO HIGH LIGHT INTENSITIES

Chloroplasts are considered to be the most powerful source of ROS in plants even under normal conditions [74]. Under excess light conditions ( $\geq 1000 \mu\text{mol photons m}^{-2} \text{ s}^{-1}$ ), chloroplasts accept more energy than they are able to utilize. Thus, the electron transport chain in chloroplasts becomes overreduced and enzymatic processes for  $CO_2$  fixation become the rate-limiting step. As a result, photosynthesis produces more NADPH and ATP than is necessary; consequently, a lack of respective acceptors occurs. Such accumulation of redox and energy equivalents reduces the plastoquinone pool and/or inhibits the water-splitting complex, inevitably leading

to PSII inactivation, so-called photoinhibition [75–79]. Exposure to high light intensities leads to higher intracellular levels of ROS due to increased rates of  $O_2$  photoreduction in chloroplasts and increased flux of  $H_2O_2$  in peroxisomes via photorespiration [80,81]. Nonfunctional PSII is also known to generate  $^1O_2$  in high quantities [82].

In a broad range of plant species, a strong correlation has been reported between the intensity of the light environment and foliar activities of a number of antioxidant enzymes and contents of ascorbate and glutathione [83–85]. It has been suggested that enhancements in the activities of activated-oxygen-scavenging enzymes during high light stress occur mostly in the chloroplasts [43]. This could be supported by the fact that tobacco plants overexpressing chloroplast Cu/Zn SOD were less sensitive to photoinhibition than nontransgenic controls [86]. However, the exposure of *Arabidopsis* plants to light stress triggered ROS production not only in the chloroplast but also in the cytosol [87].

The rapid increase in SOD activity and the gradual increase in the activities of APX, GR, DHAR, and MDHAR were observed in whole cells in *Begonia x erythrophylla* when exposed to high light [88]. On the other hand, it has been reported that both the synthesis and degradation of CAT are light sensitive [89], and the light impairment of CAT activity was described [90]. The decline in CAT activity combined with the rapid oxidation of both the ascorbate and glutathione pools, and the rapid increase in SOD activity that would have resulted in the rapid conversion of  $O_2^{\cdot-}$  to  $H_2O_2$ , could have resulted in the rapid increase of cellular  $H_2O_2$ . A reduction in CAT activity could also lead to lowered breakdown of the  $H_2O_2$  formed as a result of photorespiration and mitochondrial electron transport [88].

As regards low molecular antioxidant response to excess light, several deficient mutants were investigated. Leaf disks of the *Arabidopsis thaliana* mutant *vte1*, which is deficient in tocopherol cyclase activity resulting in a complete lack of tocopherols, were suddenly exposed to an intense white light, due to which chlorophylls and lipids were rapidly photooxidized, but no such alterations were observed in tocopherol-containing wild-type leaf disks [91]. The *vte2* mutant, which accumulates only 10%–30% of the wild-type level of ascorbate [92,93], is also sensitive to high light and shows bleaching when transferred from low light to high light [94,95].

## 6.8 UV RADIATION

UV radiation can be divided into three classes according to its energy: UV-A, UV-B, and UV-C. UV-A (315–400 nm) is not attenuated by atmospheric ozone, and this less damaging radiation is an important photomorphogenic signal in plant development [96]. UV-B (280–315 nm) is strongly absorbed by atmospheric ozone; however, incident UV-B radiation in low layers in the troposphere is increasing due to the reduction in the stratospheric ozone concentration [97]. Highly energetic UV-C (wavelengths  $\leq 280$  nm) is strongly absorbed by oxygen and ozone in the stratosphere such that none of this sterilizing radiation is present in terrestrial sunlight.

Many of the effects of UV-B on plants are likely to be more or less a direct result of cellular damage caused by aberrant photoproducts in macromolecules such as DNA [98] and proteins [99,100]. Not least, UV-B radiation induces the production of ROS [101]. The most common protective mechanism against the potentially damaging effect of the irradiation is the biosynthesis of UV-absorbing compounds [102], which include different classes of flavonoids. Flavonoids accumulate in the vacuoles of epidermal cells where they attenuate the UV component of sunlight with minimal absorption of photosynthetically active radiation [103,104]. As was mentioned above, flavonoids are strong antioxidants, and most flavonoids outperform even well-known antioxidants, such as ascorbate and  $\alpha$ -tocopherol, in in vitro assay [105].

Exposure of *Nicotiana plumbaginifolia* to UV-B strongly increased CAT and GPX (glutathione peroxidase) mRNA, but APX and SOD transcript levels remained unaltered [106]. The SOD activity increased and the CAT activity decreased both in green and in etiolated barley seedlings [107]. In cucumber (*Cucumis sativus* L.) cotyledons, UV-B enhanced the activity of SOD peroxidase as well as the ascorbate content, but decreased the level of  $\alpha$ -tocopherol [108].

Transgenic plants overexpressing enzymes involved in ROS scavenging are very often more tolerant to UV-B radiation. Examples of such plants are the methyl viologen-resistant *Arabidopsis* mutant (*rcd1-2*), with enhanced activity of plastidic Cu/Zn SOD and stromal APX [109], and tomato (*Lycopersicon esculentum*) overexpressing cytosolic APX [110].

*Arabidopsis* mutant (*tt5*), which is flavonoid deficient, synthesized new isoforms of APX after UV-B irradiation [111]. Rao et al. suggested that UV-B exposure preferentially induces peroxidase-related enzymes.

As mentioned above, UV-C is not present in terrestrial sunlight; however, it has been employed experimentally to induce strong oxidative stress. SOD, APX, CAT, and GR activities markedly increased in UV-C irradiated bean (*Phaseolus vulgaris* L.) cotyledons. With prolonged irradiation, the activities of SOD, APX, and GR started to decrease, but CAT activity henceforward increased [112]. In these cotyledons,  $\beta$ -carotene and zeaxanthin increased, but ratios between reduced and oxidized ascorbate, as well as between reduced and oxidized glutathione sharply decreased [113].

## 6.9 SALINITY STRESS

Salinity affects almost all aspects of plant development: germination, vegetative growth, or reproduction. Soil salinity imposes ion toxicity, osmotic stress, nutrient deficiency, and oxidative stress in plants. Sodium accumulation in cell walls can rapidly lead to osmotic stress and cell death [114]. High salt concentrations in soil impose osmotic stress and, thus, limit water uptake from soil. Ion toxicity is the result of replacement of  $K^+$  by  $Na^+$  in biochemical reactions, and  $Na^+$  and  $Cl^-$  induced conformational changes in proteins. For several enzymes,  $K^+$  acts as a cofactor, which cannot be substituted by  $Na^+$ . High  $K^+$  concentration is also required for the binding of tRNA to the ribosomes, and thus protein synthesis is affected [115]. Ion toxicity causes metabolic imbalances, which in turn leads to oxidative stress [116].

Increases in activities of SOD, APX, and GR under salinity stress have been observed in many species [117–119]. However, this statement is not user type: while both CAT and APX activities declined and that of SOD increased in tobacco leaves, activities of GR and APX increased while the SOD activity decreased in the roots of the same plants [10].

Relatively higher Cu/Zn SOD, Fe SOD, APX, and GR activities in the chloroplastic fraction and Mn SOD in the mitochondrial fraction in tolerant wheat genotypes have also been reported [120]. NaCl enhanced both mRNA expression and activities of Mn SOD, APX, GR, and MDHAR in tolerant pea cv. Granada, whereas a significant change was neither observed in mRNA levels nor in the activities of those enzymes in salinity-sensitive cv. Chillis [121]. Similarly, in chloroplasts from tolerant pea plants, the NaCl stress induced a significant increase in Cu/Zn SOD and APX activities as well as in the ascorbate content, while in chloroplasts from sensitive plants, NaCl evoked increases in the  $H_2O_2$  content and lipid peroxidation and no changes were observed in the enzymatic activities [122].

Transgenic tobacco overexpressing GR did show increased levels of lipid peroxidation under salinity stress [123]. On the other hand, overexpression of APX in tobacco chloroplasts enhanced the tolerance to salt stress [124]. Also, transgenic rice overexpressing Mn SOD was more tolerant against salinity stress compared to wild type [125].

As a protection against salt stress, plants accumulate various osmolytes for maintaining ionic homeostasis, for example, proline, mannitol, pinnitol, ononitol, and sorbitol in cytosol. Simultaneously, these organic osmolytes have also been proved to be antioxidants: the presence of mannitol in chloroplasts can protect plants against oxidative damage by hydroxyl radicals [126]. Similarly, exogenous proline decreased the rate of lipid peroxidation, the content of superoxide radical, and, consequently, SOD activity (almost fivefold), and increased the content of chlorophylls (*a* and *b*) in the leaves of halophyte *Mesembryanthemum crystallinum* [127].

## 6.10 HEAVY METALS

As a consequence of industrial development, the environment has been increasingly polluted with heavy metals [128]. Their toxicity comprises the inactivation of biomolecules either by blocking essential functional groups or by displacing essential metal ions [129]. The binding of metals to sulfhydryl groups in proteins is important, leading to an inhibition of activity or the disruption of a structure [130]. In addition, an excess of heavy metals may stimulate the formation of ROS [131,132], and oxidative stress caused by exposure to heavy metals has been reported many times [133–137]. Certain heavy metals like Cu and Fe exert toxicity by their participation in redox cycles, producing hydroxyl radicals in Fenton reaction [138]. On the contrary, Cd is not redox active and, thus, unable to participate directly in Fenton-type reactions [139], but can indirectly initiate the production of different ROS by unknown mechanisms, giving rise to an oxidative burst [140–143].

The changes in activities of antioxidant enzymes depend on the duration, the type of metal, and the strength of stress treatment. In sunflower (*Helianthus annuus* L.), CAT activity decreased to 24% and 70% of the control activities in Cu- and Cd-treated leaf disks, respectively. APX activity behaved similarly. SOD activity decreased to 50% and 27% after Fe and Cd treatments, respectively [134].

In pea plant leaves treated by 50  $\mu$ M CdCl<sub>2</sub>, CAT and SOD activities decreased, but GR activity did not show significant changes. A strong reduction of chloroplastic and cytosolic Cu/Zn SODs by Cd was found, and Fe SOD to a lesser extent, while Mn SOD was the most resistant isoform at 40  $\mu$ M Cd. To determine if the observed reduction in the SOD activities was due to a direct interaction of Cd with the enzymes, commercial Cu/Zn SOD and pea leaf extracts were incubated with 100  $\mu$ M Cd for 24 and 72 h, respectively. In these conditions, no effect by Cd on the Cu/Zn SOD activity was detected even after 72 h incubation. CAT isoenzymes responded differentially, the most acidic isoforms being the most sensitive to the Cd treatment [139].

Roots and leaves of pea plants exposed to 4 and 40  $\mu$ M of Cd for 7 days in hydroponic culture responded differently. Cd-induced enhancement in SOD activity was higher at 40  $\mu$ M than at 4  $\mu$ M concentration in leaves. While CAT activity prominently increased in leaves both at 4 and 40  $\mu$ M Cd, APX showed maximum stimulation at 40  $\mu$ M Cd in roots. Enhancement in GR activity was also more at 40  $\mu$ M than at 4  $\mu$ M Cd in roots. While GPX activity decreased in roots and remained almost unmodified in leaves, glutathione S-transferase showed pronounced stimulation in both roots and leaves of pea plants exposed to 40  $\mu$ M Cd [144].

After prolonged Pb stress, the activation of SOD and CAT was induced in extracts from pea roots [145]. With increased duration of treatment and Pb<sup>2+</sup> concentration, the activities of SOD, CAT, and APX increased as well. The root cells redox state of glutathione, expressed as the ratio of GSH/GSSG, dropped proportionally to Pb stress intensity [146]. Similarly, in maize (*Zea mays* L., cv. Samodek) callus cultures exposed for a long period (22 months) to Pb (0.5 mM PbCl<sub>2</sub>), APX and GR activities increased [147]. The increased activity of GPX in pea in the presence of copper has been presumed to be due to its role in metal detoxification [148].

Besides being radical scavengers, flavonoids are also able to function as chelators for metals [149]. In cell cultures of *Ginkgo biloba*, flavonoids accumulated up to 12-fold in response to Cu treatment [150]. Similarly, in callus cultures of the legume plant *Ononis arvensis*, flavonoid level increased after both Cu and Cd treatments [151].

## 6.11 AIR POLLUTANTS

O<sub>3</sub> is an important protective component against UV-C radiation in the stratosphere, but it is one of the most notorious air pollutants in the troposphere. It enters the plant cell through the stomata and breaks down in the apoplast to produce different ROS [152]. The flux of O<sub>3</sub> in the leaf interior is controlled almost entirely by stomatal conductance [153]. O<sub>3</sub> is a strong oxidant, and ROS are first observed in guard cell chloroplasts and membranes, and later they spread to the neighboring cells [154].

The increase in the ROS level in guard cells limits further diffusion of ozone into the leaf by promoting stomatal closure. Acute exposure to O<sub>3</sub> often results in foliar lesion, such as chlorosis and necrosis [155], whereas accelerated leaf senescence has been observed for chronic exposure to low ozone levels [156].

O<sub>3</sub> is considered to react first with oxidizable constituents of the apoplast, most probably through the action of apoplastic NADPH oxidase [157]. Subsequently, if O<sub>3</sub> and/or its reactive products escape interception, they react with the components of the plasmalemma and cytosol [158–160].

The first detoxifying barrier, which can be considered as constitutive since it represents the antioxidant system found in the cell (apoplast + symplast) at the time of ozone attack, will scavenge ozone and its derivatives. This system is tightly linked to the level of ascorbate, and especially apoplastic ascorbate, which was primarily proposed as a good indicator for ozone tolerance. For example, the reaction of O<sub>3</sub> with apoplastic ascorbate in the leaves of *Vicia faba* was potentially sufficient to intercept a substantial proportion (30%–40%) of O<sub>3</sub> entering the plant under environmentally relevant conditions [160]. Similarly, when in an ozone-sensitive genotype of *Raphanus sativus* L. the ascorbate content was increased by supplying the biosynthetic precursor L-galactono-1,4-lactone, tolerance to O<sub>3</sub> was improved [161]. The *Arabidopsis* mutant lacking completely cytosolic DHAR—a key component of the ascorbate recycling system—was highly O<sub>3</sub> sensitive [162].

However, elevated apoplastic ascorbate levels did not seem to be sufficient to explain plant tolerance [163–165]. In fact, the antioxidative capacity of the apoplastic space is considered much weaker than that of the cell interior [166], and it can be overwhelmed by a very important ozone flux [165]. An inductive response, triggered by the ROS, takes place allowing exchanges of antioxidants between the symplastic detoxification system and the apoplast. Although the resulting increased level of symplastic ascorbate could serve as a predictor of the resistance to ozone attack [167], other molecules and the cellular ability to regenerate antioxidants could be more relevant [164,165,168].

For example, *Nicotiana tabacum* plants overexpressing chloroplastic Cu/Zn SOD or GR did not show enhanced ozone tolerance [169,170], whereas tobacco overexpressing cytosolic Cu/Zn SOD showed less leaf injury than wild-type plants (5% versus 25%, respectively) upon exposure to near-ambient ozone regimes [171]. SOD levels increased twofold in poplar hybrid after 90 min of ozone exposure (180 ppb O<sub>3</sub>). In the same poplar, reduction of photosynthesis induced by high O<sub>3</sub> concentrations was preceded by a significant increase in the foliar glutathione content, but almost 50% of the total glutathione became oxidized under these conditions [172]. Nevertheless, elevated foliar activities of glutathione synthase or GR alone were not sufficient to improve the tolerance of hybrid poplar to acute ozone stress [173].

## 6.12 CONCLUSIONS

The production of ROS during environmental stress is one of the main causes for decreases in productivity, injury, and death that accompany these stresses in plants [174]. Current data suggest certain correlation between plant antioxidants and plant stress tolerances; however, it is impossible to draw general conclusions. Ambiguity of some results is probably caused by different designs of experiments and different ages of plants when they are exposed to a particular stress. Also, the impact of a stress on a plant differs; hence, the plant responses are different as well. The reaction of a plant cell to adverse conditions is probably cross talk among responses of individual organelles and compartments. Moreover, we have to consider also other important regulators of plant responses to stresses, namely, hormones. They mutually regulate stress response.

In nature, the antioxidant response depends not only on the stress length and intensity but also on stress combination—plants are rarely exposed to one stress only *au naturel*. Slow progress in breeding for abiotic stress-tolerant crops can be attributed to the poor understanding of the molecular mechanisms associated with tolerance against combined stresses. Further research is necessary to better understand the role of antioxidants in combination with various abiotic stresses.

During the past decade, applications of molecular tools, such as gene knockout or transgenic approaches, have improved our understanding of plant stress defense. There is no doubt that the utilization of transgenic plants grown under either single stress but better under-stress combinations that occur in nature will uncover many important developments, which will contribute in increasing crop production.

## 7.1 OXIDATIVE REACTIVE SPECIES PARADIGM: REDOX SIGNAL TRANSDUCTION VERSUS ANTIOXIDANTS STRESS RESPONSE

It is believed that over 2.2 billion years ago, the presence of O<sub>2</sub> in the Earth's atmosphere was originated due to the evolution of cyanobacteria photosynthetic activity, which used the sun's energy and water to produce sugars with the release of O<sub>2</sub>. Since then, several organisms began to evolve an antioxidant defense that gives them the capacity to tolerate O<sub>2</sub> and use it for metabolic transformation and biosynthesis (Halliwell 2006, Slesak et al. 2007). Considering the relationship between aerobic organisms and O<sub>2</sub>, it is remarkable that this molecule can be both beneficial and damaging. Beneficial for the reason that O<sub>2</sub> is essential as electron exchanger for an efficient respiration and photosynthetic activity and it is largely used for signal transduction; while damaging because O<sub>2</sub> can cause dysfunction on cell components by irreversible modifications on DNA, proteins, sugars, and lipids. Hence, there is a balance/imbalance between both sides, which is critical for the cell functionality and survival (Slesak et al. 2007).

During evolution in an aerobic atmosphere, which unavoidably exposes organisms to an oxidative environment, plants and all other aerobic life-forms evolved different antioxidative systems to protect cell components. Consequently, a delicate homeostasis between oxidative and reductive reactions is maintained inside cells, which is critical in the use of O<sub>2</sub> in metabolic pathways. The presence of intracellular oxidative and reducing species determine a transitory redox environment, defined as the summation of the reduction potential and reducing capacity of the linked redox couples occurring inside the cell (Schafer and Buettner 2001). When this redox environment suffers, an imbalance and reduced or oxidized species are favored, cells are exposed to a redox stress. Both oxidative and reductive stress can trigger redox cascades that bring changes in the oxidized/reduced status of biomolecules. Changes in the cellular redox environment can alter signal transduction, DNA and RNA synthesis, protein synthesis, enzyme activation, and even regulation of the cell cycle. Thus, the redox environment might determine if a cell will proliferate, differentiate, or perish (Moller et al. 2007, Neill et al. 2002). Figure 7.1 schematizes how different agents can create stress conditions and also molecular damages, the whole situation challenging the cell to trigger defense mechanisms. On the other hand, Figure 7.2 shows a simplified scenario of different metabolic routes related with the flux of redox equivalents operating under physiological conditions as well as to coping situations of oxidative stress.

The use of O<sub>2</sub> in metabolic reactions through electron transport chains such as in photosynthesis and respiration produces NADPH and energy (ATP), but also generates different reactive oxygen species (ROS) as by-products (Apel and Hirt 2004, Buchanan and Balmer 2005) (Figure 7.1). ROS are different oxygen-derived species; for example, free radicals containing one or more unpaired electrons such as superoxide anion radical (O<sub>2</sub><sup>•−</sup>), hydroxyl radical (•OH), per-hydroxyl radical (HO<sub>2</sub><sup>•</sup>), singlet oxygen (<sup>1</sup>O<sub>2</sub>), and nonradical derivatives such as hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) (Foyer et al. 2009).

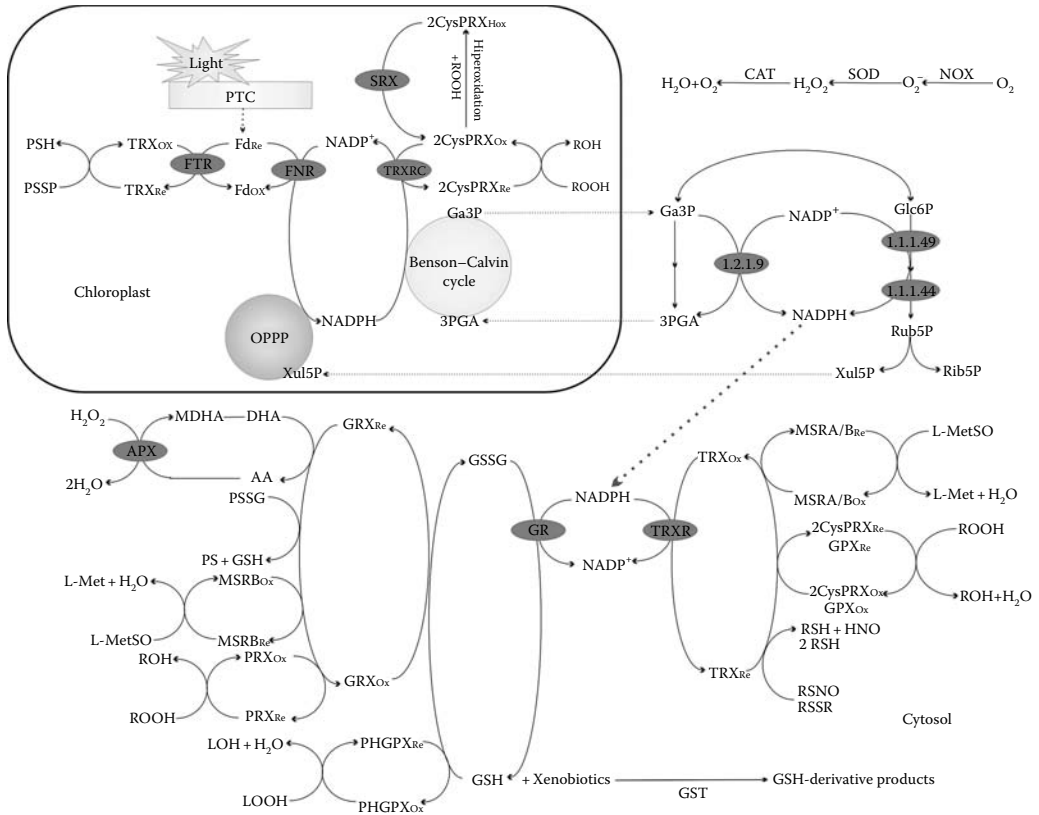

**FIGURE 7.1** Redox homeostasis, redox signaling, and oxidative stress. The scheme shows a probable progression of the cellular response elicited by synthesis of oxidant species. Different modifications triggered by oxidants are interrelated in order to increase the activity of antioxidant systems which might struggle to return the system to homeostasis.

In addition, plants may also be exposed to reactive nitrogen species (RNS) and reactive sulfur species (RSS) (Figure 7.1). The major RNS in the cell is nitric oxide ( $\cdot\text{NO}$ ) that can react with  $\text{O}_2$ ,  $\text{O}_2^{\cdot-}$ , oxidized glutathione (GSSG), and transition metals generating peroxynitrite ( $\text{ONOO}^-$ ), nitrosoglutathione (GSNO), and metal-NO adducts, respectively (Neill et al. 2008). Other components like ozone ( $\text{O}_3$ ), nitric dioxide ( $\text{NO}_2$ ), and sulfur dioxide ( $\text{SO}_2$ ), which are major air pollutants, can cause oxidative modifications as well (Moller et al. 2007).

To struggle with this different oxidative species, aerobic organism has developed an antioxidant network composed by many antioxidant systems (Figure 7.1). The term “antioxidant” can be considered to describe any compound capable of quenching ROS without itself undergoing conversion to a destructive radical (Noctor and Foyer 1998). The antioxidant network is composed by numerous proteins, enzymes, and metabolites that act in synchrony to ameliorate oxidative stress situations. Some of the proteins/enzymes acting in plant antioxidative networks are catalase (CAT), peroxiredoxin (PRX), thioredoxin (TRX), glutaredoxin (GRX), and sulfiredoxin (SRX) whereas main metabolites involved include ascorbate, glutathione (GSH), tocopherol, and NAD(P)H. The enzymatic and nonenzymatic antioxidant components work together to form different groups of antioxidant systems.

Plants, as photosynthetic aerobic organisms, are highly exposed to oxidative conditions. Moreover, due to their sessile lifestyle, plants are unconditionally exposed to a range of biotic and abiotic deleterious stresses that can trigger an oxidative burst. Besides, these oxidative species can function initially as signal transducers (Figure 7.1). The situation of oxidative stress depends on the sort of ROS that is produced, the concentration and the site where molecules are generated, their interaction with other molecules present in the organism, as well as the developmental stage and the past of the cell (Moller et al. 2007). Accumulation of  $\text{H}_2\text{O}_2$ , for example, is perceived by the plant as a signal of environmental change. As a diffusible signal-transducer molecule,  $\text{H}_2\text{O}_2$  alerts metabolism to the presence of both biotic and abiotic threats (Noctor and Foyer 1998). If the plant response is not enough to overcome this threat, the oxidative stress is established. Comprehension of occurrence and function of antioxidant metabolic routes is of high interest to understand (1) how plants detoxify oxidative species, (2) how they rearrange the whole metabolism under oxidative conditions, (3) how signal transduction pathways operate in response to oxidative stress, and (4) how cells repair macromolecules after oxidative damage.

**FIGURE 7.2** Cross talk between antioxidant systems. The scheme shows fluxes between main redox components in plants.  $O_2$ : molecular oxygen,  $O_2^-$ : superoxide anion,  $H_2O_2$ : hydrogen peroxide,  $H_2O$ : water, NOX: NADPH oxidase SOD: superoxide dismutase, CAT: catalase, PTC: photosynthetic transport chain, Fd: ferredoxin, FNR: ferredoxin-NADP oxido-reductase, FTR: ferredoxin-thioredoxin oxide-reductase, TRX: thioredoxin, PSH: thiol-protein, PSSP: disulfide-protein, TRXRC: thioredoxin reductase C, 2CysPRX: typical two cysteine peroxidoreductase, ROOH: peroxide, ROH: alcohol, SRX: sulfiredoxin, Ga3P: glyceraldehyde-3-phosphate, 3PGA: 3-phosphoglycerate, (1.2.1.9): non-phosphorylating glyceraldehyde-3-phosphate dehydrogenase, Glc6P: glucose-6-phosphate, (1.1.1.49): Glc6P dehydrogenase, (1.1.1.44): 6-phosphogluconate dehydrogenase, Rub5P: ribulose-5-phosphate, Rib5P: ribose-5-phosphate, Xul5P: xylulose-5-phosphate, OPPP: oxidative pentose phosphate pathway, GR: glutathione reductase, GSSG: oxidized glutathione, GSH: reduced glutathione, GRX: glutaredoxin, DHA: dehydroascorbate, AA: ascorbic acid, APX: ascorbate peroxidase, MDHA: monodehydroascorbate, PSSG: glutathionyl-protein, MSRB: B-type methionine sulfoxide reductase, L-MetSO: L-methionine sulfoxide, L-Met: L-methionine, PRX: peroxidoreductase, PHGPX: phospholipid hydroperoxide glutathione peroxidase, LOOH: lipid hydroperoxide, LOH: lipid alcohol, TRXR: thioredoxin reductase, MSRA: A-type methionine sulfoxide reductase, GPX: glutathione peroxidase, RSNO: S-nitrosothiols, RSSR: low molecular weight disulfide, RSH: low molecular weight thiol, HNO: nitroxyl, GST: glutathione-S-transferase.

## 7.2 OXYGEN, NITROGEN, AND SULFUR REACTIVE SPECIES: VERSATILITY OF OXIDANT MOLECULES

Oxidant species include a great number of reactive molecules chemically derived from partial reduction of oxygen, nitrogen, or sulfur (Giles et al. 2001, Nordberg and Arner 2001). Production of these molecules is a natural, constant, and inevitable process linked to cellular metabolism and to the interaction of the cell with its environment (Apel and Hirt 2004) (Figure 7.1). Some of these molecules (singlet oxygen, hydroxyl radical, peroxynitrite, or sulfenic acid) are extremely

reactive, while others (superoxide anion and hydrogen peroxide) are reactive but in a smaller degree (Giles and Jacob 2002, Nordberg and Arner 2001, Patel et al. 1999). Oxidant species have the potential to cause oxidative damage by reacting with many biomolecules (Figure 7.1), being able not only to modify their structures but also to produce a loss in their specific biological functions (Apel and Hirt 2004, Friguet 2006). Recently, it has become apparent that oxidant species have roles as signaling molecules (Figure 7.1) that contribute to the control of plant development, in the sensing of external environment and in the defense against pathogens (Forman et al. 2004, Foyer and Noctor 2005, Pauly et al. 2006, Vranova et al. 2002).

## 7.2.1 REACTIVE OXYGEN SPECIES

ROS include a number of chemically reactive molecules derived from oxygen, such as oxygen ions, free radicals, and peroxides, both inorganic and organic (Forman et al. 2004); all of them being highly reactive due to the presence of electrons at unpaired valence shell. ROS are generated as natural products of the normal metabolism of oxygen and have important roles in cell signaling and oxidative stress (Hancock 1997, Kotchoni and Gachomo 2006, Neill et al. 2002). Next, the most common intracellular forms of ROS are described.

### 7.2.1.1 Singlet Oxygen

Singlet oxygen ( $^1\text{O}_2$ , diamagnetic form of molecular oxygen), can be generated by an input of energy that rearranges electrons in its valence shell (Halliwell 2006). Because of the differences in their electron shells, singlet and triplet oxygen ( $^3\text{O}_2$ , most stable form of molecular oxygen) differ in their chemical properties (Halliwell 2006). In  $^1\text{O}_2$ , the spin restriction is removed and the oxidizing ability greatly increased, being able to directly oxidize proteins, DNA, and lipids (Triantaphylides and Havaux 2009). Note that  $^1\text{O}_2$  is not a free radical, since it has no unpaired electron. In plants, insufficient energy dissipation during photosynthesis can lead to the formation of a chlorophyll triplet state that can transfer its excitation energy to ground-state  $\text{O}_2$  to form  $^1\text{O}_2$  (Halliwell 2006, Triantaphylides and Havaux 2009). This can oxidize chloroplast molecules and also trigger cell death. Plants have molecules that can quench the  $^1\text{O}_2$ , such as carotenoids, tocopherols, plastoquinones, ascorbate, vitamin B6, and flavonoids (Triantaphylides and Havaux 2009). The  $^1\text{O}_2$  is also sometimes used as a signaling molecule, having a crucial role in plant responses to light (Halliwell 2006, Triantaphylides and Havaux 2009).

### 7.2.1.2 Superoxide Anion

Superoxide anion ( $\text{O}_2^{\cdot-}$ ) is the product of the one-electron reduction of  $\text{O}_2$ , which occurs widely in nature (Vranova et al. 2002). With one unpaired electron,  $\text{O}_2^{\cdot-}$  is a free radical that is paramagnetic (as is the case for  $\text{O}_2$ ) (Apel and Hirt 2004, Forman et al. 2004); even so, it is not highly reactive, lacking the ability to penetrate lipid membranes and therefore remaining trapped within the compartment where it is generated (Nordberg and Arner 2001). Formation of  $\text{O}_2^{\cdot-}$  takes place spontaneously, especially in electron rich aerobic environments in the vicinity of the mitochondria inner membrane (Nordberg and Arner 2001). It can also be produced endogenously by flavoenzymes, such as NADPH oxidase, lipoxygenase, and cyclooxygenase (Kotchoni and Gachomo 2006).  $\text{O}_2^{\cdot-}$  has important roles both in redox signaling response to different stimulus and in defense against pathogens (Kotchoni and Gachomo 2006). Because  $\text{O}_2^{\cdot-}$  is toxic, almost all living organisms contain isoforms of superoxide dismutase (SOD) (Apel and Hirt 2004), an extremely efficient enzyme that catalyzes dismutation of two molecules of  $\text{O}_2^{\cdot-}$  into hydrogen peroxide and  $\text{O}_2$  (Apel and Hirt 2004).

### 7.2.1.3 Hydrogen Peroxide

Even when hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) is not a free radical, its damaging capacity is important after its ability to penetrate biological membranes (Apel and Hirt 2004, Bienert et al. 2006, Neill et al. 2002). It plays a role as an intermediate in the formation of other ROS, including HOCl (hypochlorous acid)

and  $\cdot\text{OH}$  (formed via oxidation of transition metals, see below) (Nordberg and Arner 2001).  $\text{H}_2\text{O}_2$  is moderately reactive and relatively stable (half-life of  $10^{-3}$  s), exhibiting remarkable diffusion capacity (Neill et al. 2002). It can function as an intracellular signaling molecule inducing a wide range of molecular, biochemical, and physiological responses within cells (Hancock 1997, Neill et al. 2002).  $\text{H}_2\text{O}_2$  can inactivate enzymes through oxidation of their thiol groups. Generation of  $\text{H}_2\text{O}_2$  in plants is induced following exposure to a wide variety of abiotic and biotic stimuli, like extreme temperatures, UV irradiation, excess of excitation energy, exposure to ozone, phytohormones (i.e., ABA), dehydration, wounding, and pathogen attack (Apel and Hirt 2004, Kotchoni and Gachomo 2006, Neill et al. 2002). Potential sources of  $\text{H}_2\text{O}_2$  include  $\text{O}_2^{\cdot-}$  dismutation by SOD, NADPH oxidase, cell-wall peroxidase, amino oxidase, oxalate oxidase, and flavin-containing oxidase (Neill et al. 2002).  $\text{H}_2\text{O}_2$  is removed by at least four antioxidant enzyme systems, namely, catalases, glutathione peroxidases, ascorbate peroxidases (APXs), and peroxiredoxins (PRXs) (Forman et al. 2004, Noctor and Foyer 1998).

#### 7.2.1.4 Hydroxyl Radical

Hydroxyl radical ( $\cdot\text{OH}$ ) has a very short half-life (approx.  $10^{-9}$  s), and is an extremely dangerous compound to organisms because of its strong reactivity toward biomolecules (Halliwell 2006, Nordberg and Arner 2001). This radical species is capable of damaging biological systems to higher extent than any other ROS. Unlike  $\text{O}_2^{\cdot-}$ , which can be detoxified by SOD, the  $\cdot\text{OH}$  cannot be eliminated enzymatically (Halliwell 2006). As the diffusion rate is slower than the half-life, this species will react with any oxidizable compound in its vicinity. It can damage almost all types of macromolecules: carbohydrates, nucleic acids (mutations), lipids (peroxidation), and amino acids (e.g., conversion of phenylalanine to *m*- and *o*-tyrosine) (Halliwell 2006, Triantaphylides and Havaux 2009, Vranova et al. 2002). Cells utilize compounds as glutathione or ascorbate to protect important structures from  $\cdot\text{OH}$  (Noctor and Foyer 1998). This radical is formed from  $\text{H}_2\text{O}_2$  in a reaction catalyzed by metal ions ( $\text{Fe}^{2+}$  or  $\text{Cu}^+$ ), often bound in complex with different proteins or other molecules [This is known as the Fenton reaction (7.1) (Nordberg and Arner 2001)].  $\text{O}_2^{\cdot-}$  also plays an important role in connection with the Fenton reaction by recycling metal ions (7.2) (Nordberg and Arner 2001, Vranova et al. 2002). The sum of these reactions is the Haber–Weiss reaction, which illustrates the important role played by transition metals in the formation of  $\cdot\text{OH}$  (Vranova et al. 2002).

### 7.2.2 REACTIVE NITROGEN SPECIES

RNS are a family of reactive molecules derived from  $\cdot\text{NO}$  produced via the enzymatic activity of inducible  $\cdot\text{NO}$  synthase (NOS) (Besson-Bard et al. 2008). They act together with ROS to damage cells, causing the so-called nitrosative stress. RNS are also continuously produced in plants as by-products of aerobic metabolism or in response to stress (Besson-Bard et al. 2008, Shapiro 2005). Nitration of proteins and lipids represent key biologically relevant redox signaling and injury events (Neill et al. 2002). These processes involve the participation of  $\cdot\text{NO}$ -derived species such as peroxyntirite ( $\text{ONOO}^-$ ) and nitrogen dioxide ( $\cdot\text{NO}_2$ ) generated during oxidative and nitrosative stress (Droge 2002, Squadrito and Pryor 1998). Many biomolecules are oxidized and/or nitrated by RNS, including protein tyrosine residues, thiols, and unsaturated fatty acids (Droge 2002, Squadrito and Pryor 1998).

#### 7.2.2.1 Nitric Oxide

Like  $\text{O}_2^{\cdot-}$ ,  $\cdot\text{NO}$  does not directly react with most biomolecules despite its unpaired electron (Halliwell 2006, Patel et al. 1999). It easily reacts with other free radicals (i.e., peroxy and alkyl radicals), mainly generating less reactive species, thus functioning as a free-radical scavenger

[i.e.,  $\cdot\text{NO}$  has been shown to inhibit lipid peroxidation in cell membranes] (Patel et al. 1999). However, if  $\text{O}_2^{\cdot-}$  is produced in large amounts in parallel with  $\cdot\text{NO}$ , the two species react to give peroxynitrite ( $\text{OONO}^-$ ), which is highly cytotoxic (Nordberg and Arner 2001). In plants,  $\cdot\text{NO}$  can be produced by any of four routes: (1) L-arginine-dependent NOS (although this pathway has been reported in plants, neither gene, nor cDNA, nor protein related with NOS has been isolated to date.) (Corpas et al. 2004, 2006, Valderrama et al. 2007), (2) by plasma membrane-bound nitrate reductase (Corpas 2004), (3) by mitochondrial electron transport chain (Besson-Bard et al. 2008), or (4) by nonenzymatic reactions (Besson-Bard et al. 2008).

A main physiological function involves  $\cdot\text{NO}$  as an intracellular messenger, stimulating guanylate cyclase, and protein kinases (Besson-Bard et al. 2008, Shapiro 2005). It is a signaling molecule that acts mainly against oxidative stress and also plays a role in plant-pathogen interactions (Besson-Bard et al. 2008, Shapiro 2005).  $\cdot\text{NO}$  has the ability to cross cell membranes and can thereby transmit signals to other cells (Patel et al. 1999). A biologically important reaction of  $\cdot\text{NO}$  is *S*-nitrosylation, converting thiol groups (including cysteine residues in proteins) in *S*-nitrosothiols (RSNO) (Forman et al. 2004, Squadrito and Pryor 1998). *S*-nitrosylation is a mechanism for dynamic, posttranslational regulation of most or all major classes of proteins (Giustarini et al. 2004). Excessive production of  $\cdot\text{NO}$  is counteracted by its conjugation with glutathione that results in the *S*-nitrosoglutathione adduct (GSNO), which in turn can be cleaved directly by TRX systems, consuming NADPH and liberating GSH and  $\cdot\text{NO}$  (Giustarini et al. 2004, Nordberg and Arner 2001). The total effect of  $\cdot\text{NO}$  on cells redox status is clearly multifaceted; in many aspects, it functions as an antioxidant rather than an oxidant.

#### 7.2.2.2 Peroxynitrite

The nonradical, oxidant, and nitrating agent  $\text{ONOO}^-$  is able to react with diverse biomolecules in one or two-electron reactions, thus damaging a wide number of cell components, including DNA and proteins (Landino 2008, Nordberg and Arner 2001). Formation of  $\text{ONOO}^-$  *in vivo* has been described to occur by reaction of  $\text{O}_2^{\cdot-}$  with  $\cdot\text{NO}$  (Besson-Bard et al. 2008, Halliwell 2006, Nordberg and Arner 2001). Also,  $\text{ONOO}^-$  readily reacts with  $\text{CO}_2$  to form highly reactive nitroso peroxocarbonate ( $\text{ONOOCO}_2^{\cdot-}$ ), which can generate  $\cdot\text{NO}_2$  and  $\cdot\text{CO}_3^-$  (carbonate radical), two potent oxidizing agents (Halliwell 2006, Nordberg and Arner 2001, Valderrama et al. 2007). At the physiological pH,  $\text{ONOO}^-$  rapidly protonates to peroxynitrous acid ( $\text{ONOOH}$ ) (Halliwell 2006).  $\text{ONOO}^-$  can directly damage proteins, lipids, and DNA (Landino 2008, Valderrama et al. 2007); but it can also cause damage by undergoing homolytic fission to give noxious products,  $\cdot\text{OH}$  and  $\cdot\text{NO}_2$ , or rearrange to nitrate ( $\text{NO}_3^-$ ) (Squadrito and Pryor 1998).  $\text{ONOO}^-$ , directly or via its reaction products, modifies tyrosine and cysteine residues in different proteins, being able to inactivate them (Besson-Bard et al. 2008, Landino 2008).

#### 7.2.2.3 S-Nitrosothiols

*S*-nitrosothiols (RSNO) may cause many of the biological effects of  $\cdot\text{NO}$ , mainly producing *S*-nitrosylation of proteins (Forman et al. 2004). They serve as donors of nitrosonium ion ( $\text{NO}^+$ ) and  $\cdot\text{NO}$ , which proceed as signaling molecules in plant cells (Zhang and Hogg 2005). The addition of a nitroso group to the sulfur atom of cysteine residues in proteins is known as *S*-nitrosation or *S*-nitrosylation (Forman et al. 2004, Zhang and Hogg 2005). This reversible process is a form of protein posttranslational modification, which can be regulated through mechanisms analogous to phosphorylation (Giustarini et al. 2004, Zhang and Hogg 2005). Generation of *S*-nitrosothiol adducts leads to changes in activity, interaction, or subcellular location of target proteins (Giustarini et al. 2004, Zhang and Hogg 2005).

### 7.2.3 REACTIVE SULFUR SPECIES

ROS and RNS are primary oxidizing agents generated after oxidative stress (Apel and Hirt 2004, Forman et al. 2004). There is a second generation of reactive species that possess different spectrum

of activity respect to redox reactions and biological targets (Giles et al. 2001). Thus, while sulfur is usually considered part of cellular antioxidant systems, rising evidences support the formation of RSS (with suppressor properties resembling ROS and RNS) under conditions of oxidative stress (Giles and Jacob 2002, Jacob et al. 2004). Thiols, as well as disulfides, are easily oxidized to species with sulfur in higher oxidation states (Jacob et al. 2004). Such agents include sulfenyl radicals ( $\text{RS}\cdot$ ), disulfides (RSSR), sulfenic acids ( $\text{RSO}\cdot$ ), disulfide-*S*-oxides [ $\text{RS(O)SR}$ ], and disulfide-*S*-dioxides [ $\text{RS(O}_2\text{)SR}$ ] (Giles and Jacob 2002). These species modulate the redox status of biological thiols by reaction with low molecular weight thiols and thiol moieties present in proteins. Examples include evidences that  $\text{RS(O)SR}$  are able to inactivate glyceraldehyde-3-phosphate dehydrogenase and alcohol dehydrogenase, and also that RSS induce zinc release from zinc-finger domains (Giles and Jacob 2002, Jacob et al. 2004).

### 7.3 MODIFICATION OF CELLULAR COMPONENTS: OXIDATIVE DAMAGE AND SIGNAL PERCEPTION

As illustrated by Figure 7.1, exposure to physiological concentrations of reactive oxidant species induces metabolic changes leading to cell responses such as repair, adaptation, or transformation (Forman et al. 2004). Reactive species are able to cause damage, and thereby represent potentially toxic and mutagenic agents (Smirnoff 2005), being targets for such damages all major groups of biomolecules: lipids, proteins, and nucleic acids (Halliwell 2006). The oxidative reactions are mainly irreversible and may induce (in some cases) specific repair mechanisms (Moller et al. 2007). Despite their deleterious effects, reactive species also play a central role both as indicators of oxidative stress and as signaling molecules. In contrast to oxidative stress, redox signaling always involves responses specific to oxidation–reduction reactions following a reversible mechanism (Forman et al. 2004), having reactive species as second messengers involved in signal transduction.

#### 7.3.1 EFFECTS ON DNA, LIPIDS, AND PROTEINS

##### 7.3.1.1 DNA

Reactive species have been shown to be mutagenic agents by chemically modifying DNA in different ways, mainly on the nucleotide bases (Banerjee 2008). A number of alterations include cleavage of DNA, DNA–protein cross-link, oxidation of guanine to 8-hydroxyguanine, and conjugation with polyunsaturated fatty acids (PUFA) (Moller et al. 2007, Mueller and Berger 2009). In addition to mutations, oxidative DNA modifications can lead to changes in the methylation of cytosines, which is important for regulating gene expression (Moller et al. 2007). These modifications are due to reactions with ROS, especially  $\cdot\text{OH}$  (the most reactive) and  $^1\text{O}_2$  (primarily attacking guanine) (Britt 1996, Nordberg and Arner 2001). [Contrarily,  $\text{H}_2\text{O}_2$  and  $\text{O}_2^{\cdot-}$  are not reactive at all with DNA]. If repairing systems are not able to immediately regenerate intact DNA, a mutation will result after erroneous base pairing during replication (Nordberg and Arner 2001). A number of mechanisms are available for repairing DNA damage both, in the nucleus and in the mitochondria (Kimura et al. 2004). These include direct reversion of the damage, replacement of the base, and replacement of the whole nucleotide (Banerjee 2008, Britt 1996, Roldan-Arjona and Ariza 2009).

##### 7.3.1.2 Lipids

PUFAs, such as linoleic acid (18:2) and linolenic acid (18:3) are the major fatty acids in plant membranes (Smirnoff 2005). After their multiple double bonds, PUFA are excellent targets for free radical (particularly  $^1\text{O}_2$  and  $\cdot\text{OH}$ ) attack, giving rise to a complex mixture of lipid hydroperoxides (LOOH) (Moller et al. 2007, Mueller and Berger 2009). Lipid peroxidation is probably the most explored area of research when it refers to ROS. Extensive PUFA peroxidation decreases the fluidity of the membrane, increases leakiness, and causes secondary damage to membrane proteins

(Moller et al. 2007). Several products of PUFA peroxidation can form conjugates with DNA and proteins (Banerjee 2008, Nordberg and Arner 2001). In plant cells, some PUFA oxidation products function as secondary messengers either directly or after enzymatic modification (Moller et al. 2007). Enzymatic systems involving LOOH detoxification include a member of glutathione peroxidase family, the phospholipid-hydroperoxide glutathione peroxidase (Banerjee 2008). This enzyme can directly reduce lipid hydroperoxides, utilizing reduced glutathione as a reductive equivalent donor (Smirnoff 2005).

### 7.3.1.3 Proteins

Protein oxidation is defined here as a covalent modification of a protein induced by ROS, RNS, or by-products of oxidative stress (Banerjee 2008). Protein oxidation is a widespread reaction and is often used as a diagnostic marker for oxidative stress (Moller and Kristensen 2004, 2006). Most types of protein oxidation are essentially irreversible, whereas a few involving sulfur-containing amino acids are reversible (Forman et al. 2004, Halliwell 2006). Reaction of proteins with oxidant species generates modifications of the types: (1) side chains oxidation [mainly cysteine (Kiley and Storz 2004), methionine (Tarrago et al. 2009), and tryptophan oxidation (Moller and Kristensen 2006)]; (2) carbonylation (Banerjee 2008); (3) nitrosylation (Landino 2008); and (4) interaction with products of PUFA oxidation (Moller et al. 2007). These modifications can reach different degrees, producing from less active enzymes to denatured (nonfunctional) proteins.

The oxidation of the thiol group in cysteine can achieve different species, depending on the concentration and type of the reactive oxidant species and how many cysteinyl moieties are implicated. Formation of a disulfide ( $R_1-S-S-R_2$ , cystine) between two cysteine residues can be caused by several different ROS, this being an important mechanism for metabolic redox regulation (Balmer et al. 2004, Buchanan and Balmer 2005). Intra- or intermolecular disulfide bonds can be formed between thiol side chains and the reduced form can be regenerated (reconversion of cystine to cysteine) by TRX (Balmer et al. 2004, Montrichard et al. 2009) or GRX (Lillig et al. 2008, Rouhiet et al. 2008) systems. A large number of potential TRX-regulated proteins have been identified in different cellular compartments, including cytosol, chloroplasts, and mitochondria (Montrichard et al. 2009). Another type of cysteine modification is oxidation of the thiol group to higher levels, via cysteine sulfenic acid ( $R-SOH$ ), followed by cysteine sulfinic acid ( $R-SO_2H$ ). These oxidation states can be enzymatically reverted via action of SRX followed by TRX or GSH, and are probably involved in signaling pathways (Liu et al. 2006, Rey et al. 2007). The highest level of cysteine oxidation, cysteic acid ( $R-SO_3H$ ), appears to be irreversible and damaging (Kiley and Storz 2004). Cysteine can also form mixed disulfides primarily with glutathione and this might serve to protect the cysteine group against further oxidation (Rouhiet et al. 2008). Mixed disulfides can be reduced by GRXs and glutathione (Rouhiet et al. 2008).

Other amino acids can also be target of redox modification in proteins. The oxidation of methionine to methionine sulfoxide (MetSO) is another reversible modification (Banerjee 2008). The methionine sulfoxidation is reverted in a reaction catalyzed by the methionine sulfoxide reductase using TRX or GRX as the reductant (Banerjee 2008). It has been suggested that some peripheral methionine residues act as endogenous antioxidants, protecting the active site and other sensitive domains in the protein while helping to remove ROS (Petropoulos and Friguet 2006, Rouhiet et al. 2008). It has been proposed that reversible methionine sulfoxidation could constitute a key regulatory mechanism in cells (Rouhiet et al. 2008). Further oxidation of methionine to methionine sulfone (MetSO<sub>2</sub>) appears to be irreversible and destructive to the protein (Banerjee 2008).

Other two redox modifications operating for proteins are nitrosylation and carbonylation. The former is the covalent attachment of the messenger  $\cdot NO$  to the thiol moiety in cysteine, being a posttranslational modification that potentially regulates the function of proteins (Besson-Bard et al. 2008, Lamattina et al. 2003). Protein (and glutathione) thiols can react with  $\cdot NO$  derivatives to produce a range of products including disulfides, sulfenic, sulfinic and sulfonic acids, as well as S-nitrosothiols (Besson-Bard et al. 2008, Dalle-Donne et al. 2007, Shapiro 2005). Carbonylation

is an oxidative protein modification, coursing irreversibly and with derivative products commonly found in cells (Moller et al. 2007). The oxidation of a number of amino acids particularly arginine, histidine, lysine, proline, threonine, and triptophan renders free carbonyl groups (Banerjee 2008). Carbonyl derivatives can react with other side chain groups generating protein–protein cross-linking, or with other biomolecules (such as DNA and PUFA), thus modifying their biological properties (Banerjee 2008, Cattaruzza and Hecker 2008).

### 7.3.2 PROTEIN RECOVERY, REPLACEMENT, OR REMOVAL

One oxidized protein will be repaired or degraded according to the degree and type (reversible or irreversible) of chemical modification that it underwent (Friguet 2006, Moller et al. 2007). Oxidations able to be reverted include some of the modifications on cysteine and methionine (Banerjee 2008). In this way, the TRX system has been implicated in the reduction of both disulfide bridges and cystein sulfenic acid (Schurmann and Jacquot 2000, Smirnov 2005) whereas glutathione-dependent GRXs reduce both disulfide bridges and low molecular weight mixed disulfides such as glutathione adducts (Smirnov 2005). It has been shown that the oxidation of cysteine and methionine residues on proteins could contribute to the impairment of protein function and in the loss of their activity (Moller et al. 2007). In fact, methionine residues in proteins can be oxidized to methionine-S and -R sulfoxide diastereoisomeric forms, which can be catalytically reverted by peptide methionine sulfoxide reductase (MSR) enzymes MSRA and MSRB, respectively. In some cases, the latter reversion allows recovery of functionality to the modified protein (Banerjee 2008, Boschi-Muller et al. 2005, Tarrago et al. 2009). MSR enzymes were described as a very important repair system of oxidized proteins, hence contributing to regulation of the cellular redox homeostasis (Moskovitz 2005, Tarrago et al. 2009).

Oxidized proteins generally exhibit less activity and thermostability, mainly exposing their hydrophobic amino acids to the surface (Moller et al. 2007). In addition, protein damage can also be consequence of protein adducts formation with lipid peroxidation derivatives (Moller et al. 2007) and oxidation by glycation (sometimes called nonenzymatic glycosylation, which is the result of sugar bonding, such as fructose or glucose, to a protein or lipid molecule without the controlling action of an enzyme). The latter products lead to the formation of glycosylic adducts such as pentosidine or carboxy-methyl-lysine (McPherson et al. 1988).

Oxidized proteins are degraded relatively quick, probably because a change in conformation exposes more hydrophobic residues, which are better recognized by proteases (Starke-Reed and Oliver 1989). However, massive protein damage can lead to the formation of toxic aggregates; which are not only resistant to proteolysis, but can inhibit the ability of proteases to break down other oxidized proteins (Costa et al. 2007). Accumulation of oxidized protein aggregates is a hallmark of cellular aging (Friguet 2006), and it was proposed that they are a consequence of increased oxidative damage and/or of decreased degradation and repair. In the cytosol and the nucleus, the proteasome has been described as the main intracellular proteolytic pathway implicated in oxidized polypeptides degradation, and the general turnover of proteins (Moller et al. 2007). Otherwise, the Lon protease has been shown to selectively degrade oxidized proteins within the mitochondrial matrix (Friguet et al. 2008, Moller et al. 2007).

### 7.3.3 PROTEINS INVOLVED IN REACTIVE SPECIES PERCEPTION

Traditionally, proteins participating in the perception of reactive species and signal transduction have been characterized as polypeptides exhibiting a highly sensitive reversible oxidation, such as thiol/disulfide exchange (Bindoli et al. 2008, Kiley and Storz 2004). Given the reversible nature of most oxidized forms, it has been suggested that thiol modification can play roles in signal transduction that are similar to protein phosphorylation/dephosphorylation (Bindoli et al. 2008). There are several examples of proteins whose activities are modulated by thiol oxidation and reduction, but

sensors must have some specific characteristic enabling them to propagate this signal. A classical example is the OxyR transcription factor (Wang et al. 2008), which up-regulates peroxide defenses in *Escherichia coli* and a variety of other bacteria. OxyR contains two critical cysteines that are oxidized to form an intramolecular disulfide bond when cells encounter peroxide stress (Kiley and Storz 2004). Disulfide bond formation is associated with a conformational change that alters OxyR binding to DNA and allows the protein to activate the transcription of genes encoding enzymes that destroy  $H_2O_2$ , such as catalase and the alkylhydroperoxide reductase. Once concentration of  $H_2O_2$  is decreased, OxyR is reduced to reset the system (Banerjee 2008).

A wide variety of biotic and abiotic factors can induce the production of diverse reactive oxidant species. Therefore, it could be expected that perception of the oxidative signal or stress could involve different cellular components. In plants, the knowledge (at the molecular level) of oxidative signal transduction pathways, including its perception, is far from complete. Still, studies with redox-regulated proteins and proteomic analysis have provided some clues. It is known that oxidative signal-inducible I kinase (OXI1) and mitogen-activated protein kinases (MAPK) are activated by exogenous  $H_2O_2$ , but little is known about proteins that directly react with  $H_2O_2$  (Hancock et al. 2005). A proteomic approach with iodoacetamide-based fluorescence tagging of proteins in conjunction with mass spectrometric analysis was used to identify potential targets of  $H_2O_2$  in the cytosol of *Arabidopsis thaliana*. By this procedure, it was identified the cytosolic phosphorylating glyceraldehyde-3-phosphate dehydrogenase (Ga3PDHase, EC 1.2.1.12) as the most prominent modified protein.

Studies *in vitro* have shown that *Arabidopsis* Ga3PDHase is inactivated by oxidation with  $H_2O_2$ , GSSG, and GSNO; the process being reverted by dithiothreitol (DTT) and GSH (Hancock et al. 2005, Holtgreffe et al. 2008). We have kinetically characterized the oxidation of Ga3PDHase from wheat (*Triticum aestivum*) with different reactive oxidant species. Interestingly, oxidation of the enzyme with  $H_2O_2$  was 54- or 670-fold higher than with GSNO or GSSG, respectively. On the other hand, important intracellular reducing systems, such as those involving TRX or GRX, were effective for reverting damages caused by oxidants on Ga3PDHase (Piattoni, Guerrero and Iglesias, unpublished results). The possibility of reversion was limited by the degree of the enzyme oxidation, because extensive oxidative damage caused the irreversible formation of protein aggregates. After proteomic studies, it was proposed that Ga3PDHase could be involved in  $H_2O_2$  perception (Hancock et al. 2005, 2006), which is in agreement with the above experiments developed in our laboratory suggesting a physiological redox regulation (thus with sensing of  $H_2O_2$ ) of Ga3PDHase. As a whole, current information reported in plants accords with that from animals, where it was demonstrated that Ga3PDHase is a multifunctional protein, with many roles besides its enzymatic activity in glycolysis (Katoh et al. 2006, Kimura et al. 2004, Sirover 1999). Effectively, the enzyme participates in nuclear events including gene transcription, RNA transport, DNA replication, and initiation of apoptotic cell death upon nitrosylation (Azam et al. 2008, Hara et al. 2005, Katoh et al. 2006, Nakajima et al. 2007, Sen et al. 2008, Sirover 1997).

Although irreversible protein oxidation spawns loss of native structure and functional activity, recent reports demonstrated that the induced structural changes confer, to certain polypeptides, capacities to act as oxidative stress sensors. In this way, oxidized proteins become involved in several signal transduction routes (e.g., apoptosis activation), or they display “nonconventional” enzymatic activities (now acting as chaperones or transcriptional factors). In plants, as well as in mammals and some bacteria, an example of the latter is the over-oxidation of 2Cys typical peroxiredoxin (2CysPRX) (Dietz et al. 2006). 2CysPRX are peroxidases lacking prosthetic groups that mediate in the defense against oxidative stress by reducing  $H_2O_2$  and alkyl hydroperoxides (Smirnov 2005). This enzymatic activity relies on the high reactivity of two conserved cysteines, whose modification entails not only the usual thiol/disulfide exchange, but also irreversible oxidation states of the sulfur atom (to sulfinic or sulfonic acid) (Banerjee 2008, Hall et al. 2009). These changes may induce a series of posttranslational modifications, such as phosphorylation and acetylation, which contribute

to formation of high molecular mass quaternary structures with chaperone-like activity (Aran et al. 2009, Barranco-Medina et al. 2009), that further protect thermal denaturalization and act as protein activity modulator (Barranco-Medina et al. 2009, Hall et al. 2009).

## 7.4 REDUCING POWER GENERATION SYSTEMS IN PLANTS

Inside cells, the reducing power required for all detoxifying and regenerative systems derives, directly or indirectly, from NADPH or from ferredoxin. Plants exhibit some important characteristics: (1) cells are highly compartmentalized, with the occurrence of plastids and (2) the existence of two different kinds of tissues, with distinctive metabolic scenarios (photosynthetic or heterotrophic). The latter implies differences in the routes operating to produce NADPH, which are schematized in Figure 7.2.

### 7.4.1 GENERATION OF NADPH IN PLASTIDS

In plants, there are different types of plastids: those present in photosynthetic tissues, namely, chloroplasts, and those present in non-photosynthetic tissues, like amyloplasts, leucoplasts, and chromoplasts (Hudák 1997). Diversity in plastids includes specialized functions and metabolic capacities. Even more, chloroplast metabolism differs during the light or dark period. In higher plants, the production of NADPH in plastids is associated with NADP<sup>+</sup> reduction in the light (photoreduction) by the photosynthetic electron flow, or generation by the oxidative pentose phosphate pathway (OPPP) in the dark or in non-photosynthetic tissues.

During the light period, chloroplasts have an active photosynthetic activity holding NADPH as one key metabolite. Using the sun's energy, the photosynthetic electron transport chain is able to catalyze electrons transfer from water to NADP<sup>+</sup> ( $E'_{O_2/H_2O} = 815 \text{ mV}$  and  $E'_{NADP^+/NADPH} = -340 \text{ mV}$ , where  $E'$  is the midpoint oxidation-reduction potential relative to the standard hydrogen electrode at pH 7.0), which is driven by two successive photochemical reactions involving photosystem II (PSII) and photosystem I (PSI). The two photosystems are connected via an electron transport chain, which includes an integral membrane complex, the cytochrome  $b_6f$  complex. Finally, reduced ferredoxin (Fd) reduces NADP<sup>+</sup> to NADPH via an enzyme known as ferredoxin-NADP<sup>+</sup> oxidoreductase. Electron transfer from water to NADP<sup>+</sup> is coupled to proton translocation across thylakoid membranes that generate the electrochemical potential gradient driving to ATP synthesis (Bowyer and Leegood 1997).

During the dark period (as well in non-photosynthetic tissues), NADPH production inside plastids is directly linked to the OPPP (Figure 7.2) by oxidation, interconversion, and rearrangement of sugar-phosphates pools metabolites (Brownleader et al. 1997). There are two phases: (i) one oxidative (phase 1), where via two consecutive reactions glucose-6-phosphate (Glc6P) is converted to ribulose-5-phosphate (Rub5P) with the net production of NADPH and (ii) a non-oxidative phase (phase 2), involving the interconversion of pentose-P, hexose-P, and triose-P intermediaries to regenerate Glc6P in the cycle and connect it with glycolysis. In contrast to animal and yeast cells, plants have a duplicate OPPP, with one complete pathway inside the chloroplast and another one incomplete in the cytosol (which will be discussed later) (Anderson and Advani 1970, Bailey-Serres et al. 1992, Brownleader et al. 1997, Eicks et al. 2002, Kruger and von Schaewen 2003, Schnarrenberger et al. 1973, 1995). Despite the physical separation, both pathways are interconnected by specific solute transporters present in the chloroplast envelope (Eicks et al. 2002, Neuhaus and Emes 2000, Weber et al. 2005). The first reaction of the pathway is the oxidation of Glc6P by one specific dehydrogenase (Glc6PDHase, EC 1.1.1.49) to form 6-phosphoglucono- $\delta$ -lactone and NADPH. The lactone is hydrolyzed by a specific lactonase to yield the acid 6-phosphogluconate (6PG), which then undergoes oxidation and decarboxylation by a specific dehydrogenase (6PGDHase, EC 1.1.1.44) to form Rub5P and NADPH (Nelson and Cox 2004). The second phase consists of a reversible set of interconversions between phosphorylated 3-, 4-, 5-, 6-, and 7-carbon sugars, involving the enzymes

ribose-5-P isomerase (Rib5P isomerase), Rub5P 3-epimerase, transaldolase (TA), and transketolase (TK) (Debnam and Emes 1999).

With the exception of TA, the other reversible enzyme reactions are amphibolic and also play part in the Benson–Calvin cycle (Debnam and Emes 1999). Oxidation of Glc6P by Glc6PDHase is a strategic control point, to regulate the substrate partitioning between glycolysis and the OPPP. Detailed studies carried out on chloroplastidic Glc6PDHase evidenced that its activity is under coarse and fine regulatory control. The enzyme is affected by the NADPH/NADP<sup>+</sup> ratio, pH, Mg<sup>2+</sup>, and levels of Glc6P (Brownleader et al. 1997). Furthermore, the enzyme is activated in the dark (low NADPH/NADP<sup>+</sup>) by a redox mechanism involving TRX (Buchanan 1980, Scheibe 1991, Wenderoth et al. 1997). The activity of several chloroplast enzymes is known to be regulated by reversible thiol–disulfide interchange (Buchanan 1980, Scheibe 1991). During photosynthetic electron transport in the light, covalent redox modification mediated by the ferredoxin–TRX system leads to reductive activation of several stromal target enzymes: fructose-1,6-bisphosphatase, NADP-malate dehydrogenase, phosphoribulokinase, NADP-dependent glyceraldehyde-3-phosphate dehydrogenase, and others. Chloroplastidic Glc6PDHase is regulated in an opposite way by the same system, the enzyme being inactive in its reduced state (light period) (Wenderoth et al. 1997, Wendt et al. 1999). This regulation prevents futile cycles, like simultaneous carbohydrate synthesis in the Benson–Calvin cycle and catabolism by the OPPP. Thus, in accordance with its physiological role in chloroplasts, Glc6PDHase is active only during the dark phase, when NADPH supply by the photosynthetic electron flow ceases (Wenderoth et al. 1997).

#### 7.4.2 GENERATION OF NADPH IN THE CYTOSOL OF PLANT CELLS

In the cytosol of plant cells, production of NADPH is more complicated to understand than that reported in animals and yeasts. The extent to which the OPPP operates in the cytosol of higher plants is questionable. Both Glc6PDHase (Schnarrenberger et al. 1973, 1975) and 6PGDHase (Bailey-Serres and Nguyen 1992, Bailey-Serres et al. 1992) are found in the cytosol of many plant cells. However, the organization of the reversible non-oxidative phase of the pathway is far less clear. Recent studies support the absence of Rub5P 3-epimerase, Rib5P isomerase, TK and TA in the cytosol of spinach, pea, and maize leaf cells (Debnam and Emes 1999, Schnarrenberger et al. 1995). Concurrent results were reported by Kruger and von Schaewen (2003), who analyzed the complete genome from *A. thaliana* looking for the predicted subcellular localization of multiple copies of genes encoding for enzymes of the OPPP. Such an analysis identified putative cytosolic and plastidic forms of Glc6PDHase, 6PGDHase, Rib5P isomerase, and Rub5P 3-epimerase, whereas TK and TA are predicted only as plastidic enzymes. In other words, Arabidopsis has the genetic capacity to convert cytosolic Rub5P to Rib5P and Xyl5P, but any further rearrangement of the carbon backbone to regenerate fructose-6-P and triose-P only occur within plastids (Kruger and von Schaewen 2003). Similar results were reported by the group of M.J. Emes, when they analyzed the subcellular distribution of OPPP in *Brassica napus* embryos by measuring activity of the different enzymes (Hutchings et al. 2005). Given the observations regarding the cytosolic non-oxidative phase of OPPP, the extent to which it is operative is doubtful (Averill et al. 1998). To further use cytosolic pentose-P by the non-oxidative part of the OPPP, transport of the metabolite across the plastid envelope would be required, and in fact in the inner chloroplast membrane was identified a phosphate translocator protein that preferentially catalyses the counter exchange of Xyl5P, triose-P, and Pi (Eicks et al. 2002).

As in plastids, the key regulatory step in the cytosolic OPPP seems to be that catalyzed by Glc6PDHase although the characterization of the regulatory properties for this cytosolic enzyme is scarce. An early report indicated that both chloroplastidic and cytosolic Glc6PDHases are inactivated in response to light and DTT (Anderson et al. 1974). More recent works pointed out that the two cytosolic isoforms of G6PDHase exhibit differences in modulation, with one being slightly activated by reductants and the other one behaving insensitive to redox signaling (Hauschild and von

Schaewen 2003, Hutchings et al. 2005, Wakao et al. 2008, Wakao and Benning 2005). Current data make difficult to understand the exact role played by cytosolic forms of this enzyme. Arabidopsis single and double null mutants of cytosolic Glc6PDHases indicate the occurrence of alternative, compensatory mechanisms to supply NADPH in the cytosol (Wakao et al. 2008). Since the double mutant showed increased seed oil content and mass, it was concluded that a metabolic change takes place, possibly with increase in the flux of carbon through glycolysis.

In addition to the incomplete OPPP, in the cytosol of plant cells other enzymes were reported as main sources of NADPH. A particular case is non-phosphorylating glyceraldehyde-3-phosphate dehydrogenase (np-Ga3PDHase; EC 1.2.1.9) that catalyzes the irreversible oxidation of Ga3P to 3-phosphoglycerate (3-PGA), specifically using NADP<sup>+</sup> as a cofactor, thus generating NADPH according to the reaction (Habenicht 1997, Iglesias 1989):

The np-Ga3PDHase has been identified as a member of the aldehyde dehydrogenase superfamily (Habenicht 1997), and its occurrence is restricted to some specialized eubacteria (Boyd et al. 1995, Brown and Wittenberger 1971, Fourrat et al. 2007, Habenicht 1997, Iddar et al. 2005), archaeobacteria (Brunner et al. 1998), and to the cytosol of green algae and higher plants (Arnon et al. 1954, Bustos and Iglesias 2002, Gomez Casati et al. 2000, Iddar et al. 2002, Iglesias et al. 1987, Iglesias 1989, Iglesias and Losada 1988, Jacob and D'Auzac 1972, Marchal et al. 2001, Mateos and Serrano 1992, Pupillo and Faggiani 1979). The enzyme is coded by a single gene (*gapN*) and exhibits a tetrameric quaternary structure of about 200 kDa (Bustos and Iglesias 2002, Gomez Casati et al. 2000, Habenicht 1997, Iddar et al. 2002). In photosynthetic cells, np-Ga3PDHase is involved in a shuttle system for the export of NADPH photosynthetically generated, from the chloroplast to the cytosol (Kelly and Gibbs 1973). This shuttle system involves the inter-exchange of triose-P and Pi between the chloroplast and the cytosol through the triose-P/Pi translocator of the chloroplast envelope. On the other hand, the enzyme plays a key role in plants accumulating acyclic polyols (such as in celery) by supplying the NADPH necessary for the synthesis of the reduced sugars (Gao and Loescher 2000, Rumpho et al. 1983). In nongreen cells, the enzyme would couple NADPH production necessary for anabolism with glycolysis (Habenicht 1997).

The occurrence of np-Ga3PDHase in the cytosol of plant cells establishes an alternative for glycolysis (see Figure 7.2), where Ga3P can be metabolized to 3-PGA either by the couple of phosphorylating, NAD-dependent Ga3PDHase (EC 1.2.1.12), and 3-PGA kinase (EC 2.7.2.3) or by np-Ga3PDHase (Iglesias 1989, Plaxton 1996). In the first case, NADH and ATP are produced in the pathway, whereas the second route renders NADPH but not ATP (Iglesias 1989). This branch point in glycolysis is expected to be regulated in order to effectively modulate the production of energetic and reductive power within the cell (Plaxton 1996). In fact, it has been shown that, in non-photosynthetic tissues of plant cells, np-Ga3PDHase is a target for posttranslational regulation by phosphorylation (Bustos and Iglesias 2002). The phosphorylated enzyme exhibits distinctive kinetic properties after interaction with 14-3-3 regulatory proteins (Bustos and Iglesias 2003, 2005). Also, recent studies have demonstrated that the enzyme plays a pivotal role in carbon and energy metabolism in plants under both, physiological and oxidative stress conditions (Bustos et al. 2008, Rius et al. 2006). An Arabidopsis mutant lacking np-Ga3PDHase was found to have altered morphology of the siliques, inhibited glycolytic flux, decreased CO<sub>2</sub> fixation capacity, and increased oxidative stress (Rius et al. 2006). Concurrently, the absence of np-Ga3PDHase elicited an induction of Glc6PDHase activity resulting in increased levels of NADPH. These results, taken together with that obtained for the cytosolic Glc6PDHases Arabidopsis mutants support the idea that plants compensate the disruption of one pathway generating NADPH by boosting enzymes involved in alternative routes operating within the cytosol.

Another enzyme considered as NADPH producer in the cytosol of plant cells is the non-photosynthetic isoform of NADP-malic enzyme (NADP-ME; L-malate:NADP oxidoreductase

[oxaloacetate decarboxylating], EC 1.1.1.40). NADP-ME is a widely distributed enzyme involved in different metabolic pathways that catalyzes the oxidative decarboxylation of L-malate to yield pyruvate, CO<sub>2</sub>, and NADPH in the presence of a divalent cation (Drincovich et al. 2001). Cytosolic isoforms of NADP-ME have been linked to plant-defense responses and to lignin biosynthesis by providing NADPH, as well as to control pH by balancing synthesis and degradation of malate (Smirnov and Wheeler 2000). Plant non-photosynthetic, cytosolic NADP-ME has been characterized with respect to kinetics, regulation, and function (Detarsio et al. 2008, Drincovich et al. 2001, Maurino et al. 1996, 2001, Smirnov and Wheeler 2000). Utilizing genetically transformed Arabidopsis plants over-expressing rice cytosolic NADP-ME was found to have an increase in the cytosolic NADPH/NADP<sup>+</sup> ratio, which confers salt tolerance to transgenic seedlings (Cheng and Long 2007, Liu et al. 2007).

With this background, it can be concluded that NADPH production in the cytosol of plant cells is not strictly dependent on a particular system (Figure 7.2). Rather, it can be visualized as an integrated complex metabolic network in which different primary metabolic pathways interact in order to assure the supply of reducing power demands of the cell and/or to ameliorate oxidative stress situations.

## 7.5 OXIDATIVE SPECIES SCAVENGING SYSTEMS IN PLANT CELLS

### 7.5.1 ANTIOXIDANT MOLECULES AND REDOX COFACTORS

#### 7.5.1.1 Glutathione

Reduced glutathione (GSH) is a tripeptide ( $\gamma$ -glutamyl-cysteinyl-glycine) that exists interchangeably with the oxidized form, GSSG, and is vital for normal cellular function. The GSSG/GSH couple has a standard reduction potential ( $E^{\circ}$ ) of  $-240$  mV, which makes GSH a moderate reducing agent (Banerjee 2008). Reduced GSH pools are maintained by the action of the enzyme glutathione reductase (GR), a pyridine nucleotide disulfide reductase that transfers electrons from NADPH to GSSG to generate GSH (Smirnov 2005). *De novo* synthesis of GSH occurs in two ATP-dependent steps catalyzed by glutamate cysteine ligase and  $\gamma$ -glutamyltranspeptidase. In addition, certain plants contain tripeptide homologues of GSH, in which the carboxy terminal glycine is replaced by other amino acids (Noctor and Foyer 1998). GSH is found primarily in eukaryotes and gram-negative bacteria, although a select number of gram-positive prokaryotes have also been shown to utilize it (Banerjee 2008). In eukaryotic systems, approximately 90% of the intracellular GSH pool resides in the cytoplasm, with the remainder in organelles such as the mitochondria, the endoplasmic reticulum, and the nucleus (Noctor and Foyer 1998). In plant cells, biosynthesis of GSH takes place in the cytosol and the chloroplast (Smirnov 2005).

GSH is the predominant nonprotein thiol in plants and its physiological significance may be divided into two categories: sulfur metabolism and antioxidant defense (Scheibe 1991, Smirnov 2005). GSH is a product of the primary sulfur metabolism acting as a form of transport and storage of reduced sulfur and being important as antioxidant and redox buffer (Banerjee 2008, Buchanan and Balmer 2005). GSH is relevant for phytochelatin synthesis and is thus crucial for detoxification of heavy metals such as cadmium and nickel (Abhilash et al. 2009, Noctor and Foyer 1998). In addition, GSH is substrate of several enzymes (Figure 7.2), such as glutathione-S-transferases (GST) in the detoxification of xenobiotics (Kulinskii and Kolesnichenko 2009, Smirnov 2005), for glutathione peroxidase (GPX) (Dietz et al. 2006), and phospholipids hydroperoxide glutathione peroxidase (PHGPX) (Smirnov 2005) in the reduction of H<sub>2</sub>O<sub>2</sub> and LOOH, respectively. Also, it functions as electron donor for GRXs (Lillig et al. 2008) in the mixed-disulfides reduction of proteins.

#### 7.5.1.2 Ascorbate

Ascorbate (L-threo-hex-2-enono-1,4-lactone, or vitamin C) is well known for its radical-scavenging capacity and is the most abundant small, water-soluble molecule, antioxidant in plants (Smirnov 2005).

In addition to this main role, the moderately positive standard redox potential of the ascorbate/monodehydroascorbate couple ( $E^{\circ'} = 280 \text{ mV}$ ) makes this compound an excellent one-electron donor to a large variety of enzymes, in particular, oxygenases and hydroxylases (Noctor and Foyer 1998). At physiological pH, ascorbic acid (AA;  $\text{p}K_1 = 4.2$  and  $\text{p}K_2 = 11.8$ ) is predominantly present as the ascorbate anion (Banerjee 2008). The latter readily loses an electron from its *ene*-diol group to produce the monodehydroascorbate (MDHA) radical. Further oxidation results in dehydroascorbate (DHA) (Banerjee 2008). The conjugated structure of the five-atom lactone ring containing an *ene*-diol group allows stabilization of the free radical one-electron oxidation product, MDHA, by delocalization of the unpaired electron (Noctor and Foyer 1998). The ability of ascorbate to donate one electron and the relatively low reactivity of the resulting MDHA radical is the basis of its biologically useful antioxidant and free-radical scavenging activity. Paradoxically, ascorbate can also function as a pro-oxidant agent by reducing metals ions such as  $\text{Cu}^{2+}$  and  $\text{Fe}^{3+}$ . Ferrous iron thus formed can then catalyze the generation of the  $\cdot\text{OH}$  from  $\text{H}_2\text{O}_2$  by the Fenton reaction (Banerjee 2008, Halliwell 2006).

All plants and animals, except primates and guinea pigs, can synthesize ascorbic acid (Noctor and Foyer 1998). In plants, ascorbate can accumulate to millimolar concentrations in both photosynthetic and non-photosynthetic tissues. Synthesis occurs from the relatively rare sugar L-galactose via L-galactono-1,4-lactone in the Smirnoff–Wheeler–Running pathway (Linster and Clarke 2008, Smirnoff and Wheeler 2000). This two-step oxidation is catalyzed by the NAD-dependent L-galactose dehydrogenase and L-galactono-1,4-lactone dehydrogenase. L-galactose is provided as GDP-L-galactose, which itself originates through epimerization from GDP-mannose (Noctor and Foyer 1998, Smirnoff and Wheeler 2000). In the ascorbate catabolism, L-galactose is converted to oxalate, tartrate, and threonine. At the present time, the enzymes involved in the cleavage of the ascorbate C-skeleton to produce these organic acids have not been identified (Noctor and Foyer 1998).

In plant cells, the ascorbate recycling is performed by direct reduction of DHA by two molecules of GSH (Figure 7.2). This reaction is thermodynamically feasible and has been demonstrated in cell-free systems (Banerjee 2008, Meyer 2008, Noctor and Foyer 1998). In addition, plants also contain proteins with GSH-dependent DHA reductase activity (Meyer 2008, Smirnoff and Pallanca 1996). In the photosynthetic electron transport chain, electrons are derived from the photooxidation of water by photosystem II and are transferred to MDHA by ferredoxin (Smirnoff 2000). Plants have two enzymes that catalyze ascorbate oxidation: APX (Smirnoff 2005) and ascorbate oxidase (AO) (Dawson et al. 1975). The APX catalyzes the ascorbate-dependent reduction of  $\text{H}_2\text{O}_2$  to  $\text{H}_2\text{O}$  (Shigeoka et al. 2002). APX is central in the antioxidant function of ascorbate in plants, with members found in all subcellular compartments (Dawson et al. 1975). AO, a member of the blue copper oxidase family, is a glycoprotein localized at the apoplastic level (Pignocchi and Foyer 2003), its activity being higher in expanding cucurbit fruits tissues (Arrigoni 1994).

### 7.5.1.3 $\alpha$ -Tocopherol

$\alpha$ -Tocopherol is a potent lipid-soluble antioxidant that is synthesized exclusively by plants and is the most biologically active of the eight forms of vitamin E (Banerjee 2008). This antioxidant is abundant in seeds, linked with triacylglycerols in the oil bodies and probably in glyoxysomes, where they are oxidized during germination. In addition, it is very abundant in thylakoid membranes containing PUFA and are in close proximity to ROS produced during photosynthesis (Zingg 2007). The hydrophobic phytyl side chain gives  $\alpha$ -tocopherol the lipid solubility, which anchors the antioxidant chromanol ring to the membrane (Smirnoff and Wheeler 2000).

The antioxidant capacity of  $\alpha$ -tocopherol is a result of its capacity to quench free radicals by becoming a stable radical itself (Zingg 2007). The chromanol ring can donate a single electron resulting in generation of a resonance-stabilized tocopheroxyl (tocopheryl or chromanoxyl) radical. This mechanism is the basis of its ability to prevent lipid peroxidation chain reactions. The reaction between lipid peroxy radicals and tocopherol originates hydroperoxides that may be reduced by PHGPX (Shao et al. 2008). The tocopheroxyl radical can be reduced to restore  $\alpha$ -tocopherol by

other antioxidants, such as ubiquinol, ascorbic acid, and, indirectly, dihydrolipoic acid (Banerjee 2008). On the other hand, a putative non-antioxidant function has been ascribed to  $\alpha$ -tocopherol as stabilizing cellular membrane structure by interacting with polyunsaturated fatty acyl chains (Smirnov 2005).

#### 7.5.1.4 Carotenoids

Carotenoids are the most abundant pigmented plant-derived compounds, which impart the red and yellow color to fruits and vegetables (Lu and Li 2008). These compounds are isoprenoids, consisting primarily of eight joined isoprene units with a rigid backbone due to the presence of 3 to 15 conjugated double bonds, which confer antioxidant properties. Some chemical modifications include cyclization of the carbon skeleton at one or both ends (Banerjee 2008, Britton 1989). In plants, carotenoids are essential to survival; they directly participate in photosynthesis and reactions to limit vast amounts of ROS produced in chloroplasts (Lu and Li 2008). Oxygen-containing carotenoids (xanthophylls) are integral components of photosystem II (PSII) and the light-harvesting complex (Banerjee 2008). Zeaxanthin is implicated in non-photochemical quenching of excitation energy in PSII, in which excess of energy in PSII is transferred to zeaxanthin and reradiated as heat (Ivanov et al. 2008). In addition, several carotenoids participate in defense against photoinduced damage (Smirnov 2005). Both  $\alpha$ -tocopherol and ascorbic acid can reduce carotenoid radicals, which might ascribe for the observed synergistic interactions between these three important antioxidants (Banerjee 2008, Smirnov 2005).

#### 7.5.1.5 Flavonoids

Flavonoids are a group of polyphenolic compounds produced as secondary metabolites by plants (Banerjee 2008). The general structure of plant-derived flavonoids presents two aromatic benzene rings linked through three carbons that can form an oxygenated heterocycle (Smirnov 2005). A major integrant of the group is quercetin, which is the most abundant flavonoid of this class. Other examples are isoflavones (phytoestrogens), found in high abundance in legumes (Veitch 2009). Citrus contain hesperidin (a glycoside of the flavanone hesperetin), quercitrin, rutin (two glycosides of the flavonol quercetin), and the flavone tangeritin (Gattuso et al. 2007). Main flavonoids in green tea are kaempferol and catechins (catechin, epicatechin, epicatechin gallate, and epigallocatechin gallate) (Butt and Sultan 2009). Grape skins contain important amounts of flavonoids as well as other polyphenols. Both red and white wine contain flavonoids; nevertheless, since red wine is produced by fermentation in the presence of the grape skins, it contains higher amounts of flavonoids and other polyphenolics such as resveratrol (Dohadwala and Vita 2009). Chelation of redox-active metals is the principal defensive antioxidant activity of flavonoids. Thus, they prevent peroxy radical and lipid peroxidation, scavenging of hydroxyl and peroxy radicals, and quenching of superoxide radicals and singlet oxygen (Banerjee 2008).

#### 7.5.1.6 NAD(P)<sup>+</sup>

The coenzyme pyridine nucleotide, nicotinamide adenine dinucleotide (NAD<sup>+</sup>) and its phosphorylated derivative (NADP<sup>+</sup>) are the universal energy carriers performing reversible two-electron (specifically one hydride) transfer in a variety of essential metabolic reactions in all living organisms (Pollak et al. 2007). The coenzyme NAD<sup>+</sup> (oxidized form) participates mainly in oxidative reactions by accepting electrons from energy-rich substrates (e.g., in glycolysis). On the other hand, NADPH (reduced form) acts principally as electron donor in reductive biosynthetic reactions and has an important role in oxidant production and antioxidant defense in the plant cells by means of NADPH-dependent enzyme, such as NADPH oxidase and GR, respectively (Banerjee 2008). The  $E^{\circ'}$  for the two-electron reduction of the NAD<sup>+</sup>/NADH and NADP<sup>+</sup>/NADPH couples are similar (about -320 mV) (Schafer and Buettner 2001). The fact that NAD<sup>+</sup> also participates in other reactions that are not related with redox metabolism is worth mentioning. Such are the cases when NAD<sup>+</sup> is involved in protein modification processes such as poly-ADP-ribosylation of transcription

factors in the nucleus (Ziegler 2000), or in signaling pathways as a precursor of the second messenger cyclic-ADP-ribose (Guse 2004), as well as when it acts as a substrate of a group of enzymes called sirtuins (Blander and Guarente 2004). The latter use  $\text{NAD}^+$  to remove acetyl groups from histones, being implicated in the regulation of transcription, apoptosis, and stress resistance (Trapp and Jung 2006).

Biosynthesis of  $\text{NAD}^+$  in plants occurs through two metabolic pathways. It is produced either in a *de novo* pathway from tryptophan or aspartic acid, or in salvage pathways by recycling pre-formed components such as nicotinamide (Banerjee 2008, Katoh et al. 2006).  $\text{NADP}^+$  is generated by phosphorylation of hydroxyl group in the 2' position of the ribose ring that carries the adenine moiety (Banerjee 2008). In chloroplasts,  $\text{NADP}^+$  is reduced by ferredoxin- $\text{NADP}^+$  reductase in the last step of the electron chain of the light reactions of photosynthesis (Smirnov 2005). The  $\text{NADPH}$  produced is then used as reducing power for carbohydrate biosynthesis in the Benson–Calvin cycle (Smirnov 2005). The balance between the oxidized and reduced forms of nicotinamide adenine dinucleotide is called the  $\text{NAD(P)}^+/\text{NAD(P)H}$  ratio. This ratio is an important component of what is called the redox state of a cell, a measurement that reflects both the metabolic activities and the health of cells (Schafer and Buettner 2001).

### 7.5.1.7 Flavin

Flavin mononucleotide (FMN) and flavin adenine dinucleotide (FAD) participate in a variety of enzyme-catalyzed reactions as non-covalently or covalently bound redox cofactors. A characteristic property of flavins is their ability to couple one- and two-electron transfer reactions between substrates and different electron carriers. In consequence, flavins can equilibrate the reaction between quinone (oxidized), semiquinone (one-electron reduced), and hydroquinone (two-electron reduced) species with reversible electron transfer occurring across the isoalloxazine ring of the flavin. The  $E^{\circ'}$  of free FAD is  $-219\text{ mV}$  in solution (Banerjee 2008) whereas enzyme-bound flavin has an  $E^{\circ'}$  between  $+100$  to  $-400\text{ mV}$  (Schafer and Buettner 2001). The latter contributes to the fact that many oxidoreductases, called flavoenzymes or flavoproteins, are involved in a significant diversity of reactions, such as dehydrogenation, electron transfer, dehalogenation, hydroxylation, luminescence, DNA repair, and disulfide reduction (Banerjee 2008, Rouhier et al. 2002, Smirnov 2005).

The reactivity of enzyme-bound reduced flavin with  $\text{O}_2$  is influenced by the active site environment and substrate/product complexation (Miura 2001). Reaction of reduced flavin with  $\text{O}_2$  proceeds initially through a one-electron reduction of oxygen to form a flavin semiquinone and  $\text{O}_2^{\cdot-}$  pair. Subsequent events then lead to the formation of  $\text{H}_2\text{O}_2$  (Miura 2001). The ability of reduced flavins to carry out the one-electron reduction of  $\text{O}_2$  to  $\text{O}_2^{\cdot-}$  implies to flavins with intracellular oxidative stress and pathogen defense (Yoshioka et al. 2009). In addition, some flavoenzymes are involved in regulatory and signaling pathways. An example is the apoptotic inducing factor, which is a mitochondrial flavoenzyme that shows  $\text{NADH}$  oxidase and DNA binding activities (Fleury et al. 2002, Le Bras et al. 2005). Another interesting class of flavoenzymes is the structurally related cryptochromes and DNA photolyases that are activated by blue light (Muller and Carell 2009). Cryptochromes are implicated in photosensitive signaling pathways that set the circadian clock and regulate plant growth and development. Phototropins are other group of light-sensible flavoproteins that contribute to adaptive responses to blue light in plants, thus modulating a wide variety of physiological events such as plant development, seed germination, and phototropism. (Demarsy and Fankhauser 2009, Takagi 2003).

## 7.5.2 ANTIOXIDANT ENZYMES

### 7.5.2.1 Thioredoxin System

TRXs are small redox proteins (usually around 12 kDa) with two cysteine residues in its active site within the conserved WCG/PPC motif. TRX can exist either in reduced (dithiol) or in oxidized (disulfide) form (Banerjee 2008). The function of TRX as a thiol reductant is based on the fast

reaction between reduced TRX and disulfide substrates that is linked to the reductive power of NADPH and ferredoxin systems, respectively, to disulfide reduction of target proteins (Smirnov 2005). The redox potential of TRXs is critical for activity, with the value found for plant TRXs ranging between  $-285$  and  $-350$  mV (Buchanan and Balmer 2005). Plants have an unusually high number of TRX encoding genes implicated in photosynthetic regulation. The *A. thaliana* genome encodes at least 22 TRX isoforms, which are classified in six different groups: f, m, x, and y in chloroplasts, o in mitochondria, and h in several cell compartments (cytosol, mitochondria, endoplasmic reticulum) as well as outside the cell (Gelhaie et al. 2005, Montrichard et al. 2009). TRX may control the activity of enzymes, receptors, and transcription factors via its protein disulfide reductase activity; for example, photosynthetic enzymes are controlled by specific TRXs via light. TRX<sub>m</sub> and TRX<sub>f</sub> are specific for target enzymes like malate dehydrogenase and fructose biphosphatase, respectively (Smirnov 2005).

TRXs were identified as the first thiol–disulfide exchange proteins in plants (Gelhaie et al. 2005). They have a common tertiary protein structure, the so-called thioredoxin fold. The same domain structure is found in many other thiol-proteins such as the GRX, GST, GPX, PRX, and protein disulfide isomerase (Martin 1995). Reduced TRX acts to directly reduce protein disulfides by means of fast thiol–disulfide interchange reactions (Bindoli et al. 2008). Initially, reduced TRX non-covalently docks to a target protein through a hydrophobic interaction surface and hydrogen bonds between residues of the TRX backbone and the target protein. This is followed by nucleophilic attack of the thiolate of the N-termini cysteine (comprised in the CXXC active domain) on the target disulfide performing a thiol–disulfide exchange reaction and rendering a transient protein–protein complex disulfide intermediate. Then, the intramolecular attack of C-termini cysteine cleaves the disulfide forming oxidized TRX and the reduced target protein (Banerjee 2008, Buchanan and Balmer 2005).

As illustrated by Figure 7.2, in plants, TRXs are components of two redox systems found in different cell compartments (Smirnov 2005). The ferredoxin system is located in chloroplasts and involves ferredoxin (Fd, an iron–sulfur protein), ferredoxin–thioredoxin reductase (FTR) and TRX f, m, x, and y (Gelhaie et al. 2005, Schurmann and Jacquot 2000). In this system, electrons flow via thiol–disulfide exchange intermediates from Fd, reduced in the light (via photosystem I), to the target protein according to the sequence: light  $\rightarrow$  Fd  $\rightarrow$  FTR  $\rightarrow$  TRX  $\rightarrow$  target protein (Buchanan and Balmer 2005, Scheibe 1991). The system turns into oxidized form in the dark in the presence of O<sub>2</sub> (or oxidized TRX, GSSG, or ROS) (Montrichard et al. 2009). The chloroplast consequently differs from the cytoplasm in undergoing changes from a reductive state in the light to a more oxidative one in the dark (Buchanan and Balmer 2005). The FTR is the central enzyme of the ferredoxin system that transfers a redox signal received from Fd to TRX by a unique mechanism involving a 4Fe-4S cluster and a disulfide bridge, thereby transforming the signal from an “electron signal” to a “thiol signal” (Buchanan et al. 2002, Schurmann 2003).

The NADPH-dependent TRX system is localized both, in the cytosol and mitochondria (Gelhaie et al. 2005). The system includes an FAD-containing enzyme, an NADPH-dependent thioredoxin reductase (NTR, a low molecular weight thioredoxin reductase) that in *A. thaliana* exists as two identical forms (A and B, coded by two distinct genes) (Meyer et al. 2005, 2008). The two NTR have been localized in either the cytoplasm or mitochondria (Meyer et al. 2005). The enzymes transfer electrons from NADPH to TRX<sub>h</sub> (in the cytoplasm) or TRX<sub>h</sub> and TRX<sub>o</sub> in mitochondria (follow a thiol/disulfide exchange mechanism), according to the sequence: NADPH  $\rightarrow$  NTR  $\rightarrow$  TRX  $\rightarrow$  target protein (Buchanan and Balmer 2005, Gelhaie et al. 2005, Smirnov 2005). In addition, recent studies found the existence, in chloroplasts, of a modified type of NTR called NTRC. The latter presents a TRX domain in the C-terminal extension (Kirchsteiger, Pulido, Gonzalez et al. 2009). This form of NTR operates as a complete NADPH-dependent TRX system, being able to transfer reducing equivalents from NADPH to BAS1 (a plastidic 2CysPRX) (Alkhalfioui et al. 2007, Moon et al. 2006).

The number of potential functions of the TRX system cannot be detailed here and remain to be confirmed in several cases. Apart from its documented dark/light regulation, the TRX system

participates in responses against environmental stresses (Gelhaye, Rouhier, Navrot et al. 2005). The TRX system is involved in ROS detoxication at least through several PRX isoforms, GPX and MetSO reduction by means of MSRA/B proteins (Montrichard et al. 2009) (see [Figure 7.2](#)).

### 7.5.2.2 Glutathione-Dependent System

GSH is a key low molecular weight component involved in the protection of plant cells to oxidative stress (Smirnov 2005). As shown in [Figure 7.2](#), in this process, GSH is converted to its oxidized product, GSSG (Noctor and Foyer 1998). A specific flavoenzyme belonging to the disulfide oxidoreductase family, the GR reduce GSSG to GSH using NADPH as electron donor (Rouhier et al. 2008). Most of GRs are homodimeric enzymes with the active site being arranged by both subunits (Rybus-Kalinowska et al. 2009). Each monomer can be divided into three domains: the FAD, the NADP<sup>+</sup>, and the interface domain. GSSG binding site is a bridge between the interface domain of one subunit and the FAD domain of the adjacent subunit (Banerjee 2008, Rybus-Kalinowska et al. 2009).

Alternatively, GSSG can react with protein thiols to form protein–glutathione mixed disulfides (PSSG) in a process called glutathionylation or protein thiolation (Dalle-Donne et al. 2007, Rouhier et al. 2008). Glutaredoxins (GRXs or thioltransferases) are GSH-dependent enzymes responsible for the protein dethiolation reaction (Dalle-Donne et al. 2007). Glutathionylation can either inactivate or activate several enzymes (Buchanan and Balmer 2005), with this regulated and reversible process serving to modulate certain metabolic pathways and in cell signaling (Buchanan and Balmer 2005). The glutathione system (formed by NADPH, GR, GSH and GRX) often functions in parallel with the TRX system in regulating redox homeostasis in the cell.

GRX is a member of the thiol–disulfide oxidoreductase enzyme family and an important component of the GSH system (Lillig et al. 2008). It is a small protein of 10 to 24 kDa that catalyzes the reduction of proteins that are thiolated by GSH (PSSG) (Meyer et al. 2008). The reduction of PSSG is carried out by GSH, which is oxidized to GSSG and recycled to GSH via the recycling system of NADPH and GR. Thus, the electron transfer path is as follows: NADPH → GR → GSH → GRX (Smirnov 2005). It has been established that GRX can reduce protein disulfides (PSSP) using a dithiol mechanism. It can also reduce PSSG, or low molecular weight dithiols (GSSR) via either a monothiol or dithiol mechanism (Lillig et al. 2008). Approximately 30 GRX isoforms were found in *A. thaliana* (Meyer et al. 2008). According to their redox-active center, GRXs are included in three main classes: the CPYC, CGFS, and CCX[C/S] type (Rouhier et al. 2004). CC-type GRXs are only found in higher plants (Meyer et al. 2008). The redox potential of GRXs ranges between –190 and –230 mV, with these proteins performing as electron carriers in the glutathione-dependent synthesis of deoxyribonucleotides by ribonucleotide reductase (Lillig et al. 2008). In addition, GRXs participate in antioxidant defense, performing the DHA reduction (Holmgren and Aslund 1995) and serving as electron donor for several PRXs (Meyer et al. 2008) and for MSRB (Tarrago et al. 2009). Besides their function in antioxidant defense, GRXs were shown to bind iron–sulfur clusters and to deliver the cluster to enzymes on demand (Rouhier et al. 2008). Moreover, in *Arabidopsis*, GRXs are involved in flower development and salicylic acid signaling (Meyer et al. 2008, Rouhier et al. 2008).

### 7.5.2.3 Peroxiredoxin

PRXs are described as a family of thiol-based antioxidant enzymes, ubiquitously found in nature. They catalyze the reduction of H<sub>2</sub>O<sub>2</sub>, a wide variety of organic hydroperoxides (from *tert*-butyl hydroperoxide, cumene hydroperoxide, fatty acid peroxides to complex phosphatidyl choline peroxides), and ONOO<sup>–</sup> at expenses of thiol substrates, according to the equation (Banerjee 2008):

PRXs belong to the group of proteins having the thioredoxin fold, presenting the active site Cys in a TPXC motif (Dietz 2003). Furthermore, important new information on PRXs indicates that they are

not only involved in detoxification of peroxides (Figure 7.2), but also in plant-specific functions. Examples of the latter are the involvement of PRXs in the context of photosynthesis, phloem metabolism, environmental stress, pathogen resistance, proliferation, differentiation, and apoptotic pathways through both known and unknown mechanisms (Dietz 2003, Smirnov 2005).

Mechanistically, PRXs can be classified in three classes: typical 2-CysPRX, atypical 2-CysPRX, and 1-CysPRX (Poole 2007, Rouhier and Jacquot 2002). These enzymes present the same basic catalytic mechanism, in which a redox-active cysteine (the peroxidatic cysteine or R-S<sub>P</sub>H) in the active site is oxidized to a sulfenic acid (R-S<sub>P</sub>OH) by the oxidant substrate. The regeneration process of the oxidized cysteine differentiates three mechanistic classes. The typical and atypical 2-Cys PRX present a second reactive cysteine, named resolving cysteine (R-S<sub>R</sub>H), involved in generating an intersubunit disulfide bond with the sulfenic acid form of the peroxidatic cysteine (to generate R-S<sub>P</sub>-S<sub>R</sub>-R) previous to reduction. This mechanism is followed by the typical 2-CysPRX with the R-S<sub>R</sub>H on a partner subunit (Dietz et al. 2006). On the other hand, the atypical 2-CysPRX performs the same chemical mechanism (disulfide bond formation) for catalysis except that both, the R-S<sub>R</sub>H and the R-S<sub>P</sub>H, pertain to the same monomer, thus forming an intrasubunit disulfide bond previous to reduction (Smirnov 2005). The third type of PRXs, the 1-CysPRX, bypasses the disulfide bond formation prior to reduction (Banerjee 2008). The mechanism for recycling 2-CysPRX involves TRX, GRX, or another CXXC-containing redox module protein (Dietz 2003) such as CDSP32 (Rey et al. 2005), NTRC (Kirchsteiger et al. 2009), and cyclophilin (Dietz 2007). The ways for 1-Cys PRX reduction are quite uncertain, although several studies demonstrated that both, ascorbate and GSH, perform as reducing substrates (Dietz 2003). The redox potential of plastidic PRXs ranges between -307 to -325 mV (Dietz et al. 2006).

The *A. thaliana* genome contains 10 *prx* genes belonging to four different groups: 1-CysPRX, typical 2-CysPRX, PRXQ (atypical 2CysPRX), and type II PRX (atypical 2CysPRX) (Smirnov 2005). Some of the PRX transcripts have been detected in all analyzed plant tissues though the expression of each individual member of the *prx* gene family may differ significantly. The accumulation of transcripts encoding chloroplastic PRX shows a correlation with chlorophyll both in tissue distribution and during leaf development (Dietz 2003).

Even when numerous studies indicate that PRXs exclusively act as antioxidants by reducing peroxides, recent works have begun to uncover alternative roles played by these proteins (Rouhier and Jacquot 2002). Day after day evidences increase respect that H<sub>2</sub>O<sub>2</sub> is utilized as a signaling molecule to regulate a variety of important cellular functions (Neill et al. 2002, Noctor 2006, Vranova et al. 2002). As abundant and ubiquitous peroxidases, the peroxidase activity of PRXs is central in the regulation of these functions. Recent studies suggest that regulation of the peroxidase and chaperone activities of these multifunctional enzymes is an important feature for the H<sub>2</sub>O<sub>2</sub>-mediated signal transduction in plants (Hall et al. 2009). Moreover, the activity and other properties of some PRXs (particularly the typical 2-CysPRX) are regulated by over-oxidation (Banerjee 2008), nitrosylation (Romero-Puertas et al. 2007), and/or phosphorylation (Aran et al. 2009). Therefore, PRXs are probably playing a key role in modulating ROS-RNS regulatory networks as well as the intensity in the response.

Numerous evidences support that PRXs modulate plant cells signaling by several mechanisms (Dietz et al. 2006). For example, it was described that PRXs are involved in (i) modulating H<sub>2</sub>O<sub>2</sub> concentration [H<sub>2</sub>O<sub>2</sub> is a major ROS signal during adaptation and development by modifying the nuclear gene expression (Foyer and Noctor 2005)], (ii) altering lipid hydroperoxide levels [PRX can change levels of lipid peroxide-derived oxylipins that, in turn, also modulate plant responses at the level of gene expression (Mueller and Berger 2009)], (iii) detoxifying ONOO<sup>-</sup> [which mediates nitration of proteins (Aran et al. 2009)], (iv) "spending" electron donors [thus affecting redox state of other targets], and (v) regulating the redox state of interacting thiol proteins [Prx indirectly influence the redox state and possibly activity of other targets that are regulated by redox interactions with these donors]. PRXs may be considered as peroxide sensors [transmitting the information of high peroxide concentrations to other thiol proteins (Dietz 2003)], and they can

also undergo conformational changes and interact with non-thiol proteins [2CysPRX may act as molecular chaperones under oxidative conditions, interacting to non-thiol proteins and other cell structures (Aran et al. 2009, Hall et al. 2009)].

#### 7.5.2.4 Superoxide Dismutase

SODs are metalloproteins that catalyze dismutation of  $O_2^{\cdot-}$  into  $O_2$  and  $H_2O_2$ , thus representing a relevant antioxidant defense in photosynthetic cells (Smirnov 2005). *In vivo*, SOD constitutes the first line of defense against ROS, protecting cells and tissues from oxidative destruction (Hancock 1997). Plant cells have several forms of SOD, which mainly vary on the metal cofactor present: copper and zinc (CuZnSOD), manganese (MnSOD), or iron (FeSOD). CuZnSODs are generally homodimeric enzymes with a subunit molecular mass of ~16 kDa, containing one  $Cu^{2+}$  and one  $Zn^{2+}$  per subunit (Tainer et al. 1983). CuZnSODs are found in the cytosol as well as in many of the organelles of eukaryotic cells (Hart et al. 1999).  $Cu^{2+}$  constitutes the catalytic center, while  $Zn^{2+}$  provides a structural helping role (Hart et al. 1999). MnSODs localize in the mitochondrial matrix of animals and plants (Jackson et al. 1978). Mitochondrial MnSOD is a homotetrameric protein with a subunit molecular mass of 23 kDa (Jackson et al. 1978). FeSODs are constitutive enzymes that can be found in plastids (Bridges and Salin 1981).

In biological systems,  $O_2^{\cdot-}$  can undergo dismutation (velocity  $\sim 10^5 \text{ m}^{-1}\text{s}^{-1}$  at pH 7.0) (Banerjee 2008). The enzyme SOD is biologically essential because  $O_2^{\cdot-}$  reacts even faster with another biological radicals such as the NO, generating a most toxic specie, the ONOO<sup>-</sup> (Valderrama et al. 2007). SOD has the fastest turnover number of any known enzyme ( $\sim 10^9 \text{ m}^{-1}\text{s}^{-1}$ ), being this reaction only limited by the collision frequency between the enzyme and the substrate  $O_2^{\cdot-}$  (Banerjee 2008).

#### 7.5.2.5 Glutathione S-Transferase

GSTs catalyze the nucleophilic attack of GSH upon an electrophilic substrate (Smirnov 2005). GSTs participate in xenobiotic detoxification (Figure 7.2); however, they also catalyze specific reactions in a number of biosynthetic and catabolic pathways and play an important role in defense against oxidative stress by reducing ROOH and DHA (Banerjee 2008). In addition, it has been clearly established that many GSTs present GPX activity; whereas is less clear if they are involved in other reactions related with stress signaling and protein binding (Noctor and Foyer 1998). In plants, all GSTs so far described form homodimers of 50 kDa, being classified in four major groups: phi-, tau-, zeta- and theta-GST (Banerjee 2008). Recently, two additional groups were identified in *A. thaliana* (Dixon et al. 2002). The fifth group, omega-GST, is formed by four putative small DHAR with an active site represented by the CPFC/S motif (Dixon et al. 2002, Smirnov 2005). DHAR regenerates ascorbate from DHA using GSH as electron donor (Figure 7.2). The sixth subgroup, lambda-GST, comprise two members that exhibit no DHAR activity but are active as GSH-dependent thiol transferases, suggesting that they might function in dethiolation of S-glutathionylated proteins accumulated under oxidative stress situations (Dixon et al. 2002, Rouhier et al. 2008).

#### 7.5.2.6 Ascorbate Peroxidase

APX is a hemoprotein that, in contrast to catalase and GPX, appears to be a unique enzyme found mainly in plants, algae, and some protozoa (Noctor and Foyer 1998, Wilkinson et al. 2002). The enzyme participates in detoxification of  $H_2O_2$  (Figure 7.2) using ascorbate as reducing substrate, according to reaction:

APX is present in almost every compartment of the plant cell and it participates in the detoxification of  $H_2O_2$  as part of the ascorbate–glutathione or Asada–Halliwell–Foyer pathway (Hiner et al. 2002). Initially, APX activity was detected in intact chloroplasts and algae (Kelly and Latzko 1979,

Shigeoka et al. 1980). Three forms of chloroplastidic APX were reported: thylakoid-APX, stromal-APX, and soluble-APX (localized in the lumen) (Smirnoff 2000). In *Arabidopsis*, nine different genes encode APX enzymes, four of them encoding chloroplastic isozymes (Kubo et al. 1992). Two stromal APXs are dually targeted to the stroma and the mitochondrial intermembrane space (Smirnoff 2000). In addition, two different APXs are thought to be targeted to peroxisomes and glyoxysomes (Hoshi and Heinemann 2001, Nito et al. 2001) and two are localized in cytoplasm (Santos et al. 1996). Finally, there are two microsomal APXs that might bind to the external surface of glyoxysomes or be transported into peroxisomes (Lisenbee et al. 2003).

The function of APX is dependent of the availability of ascorbate and, in some cases, GSH (Smirnoff 2005). Cellular pools of these antioxidants are maintained in reduced form by enzymatic systems such as GR, DHAR, GRX, and GST (Buchanan and Balmer 2005). In addition, the enzyme presents higher affinity for  $H_2O_2$  than for organic peroxides, making it a suitable candidate to participate in the removal of the former for signaling purposes (Apel and Hirt 2004, Reddy et al. 2009). Studies with transgenic plants have demonstrated that APX is an important defense enzyme implicated in the elimination of  $H_2O_2$  (Smirnoff 2005). APX might function as component of the  $H_2O_2$ -regulation network of plants, controlling levels of the peroxide used for cellular signaling (Pauly et al. 2006). Thus, in concert with other  $H_2O_2$ -regulation enzymes of the cell, APX balances different cellular systems that generate  $H_2O_2$  in plants (e.g., NADPH oxidase in pathogen response), and also controls levels of  $H_2O_2$  used for signaling during biotic or abiotic stress (Apel and Hirt 2004, Kotchoni and Gachomo 2006).

### 7.5.3 CROSS TALK BETWEEN ANTIOXIDANT SYSTEMS

As it was described, plants have developed efficient enzymatic systems to resist/modulate damage generated by ROS and RNS. The redox cellular status is a crucial mediator for different metabolic processes acting in signaling and regulation of several metabolic and cellular processes; for example, the regulation of enzymatic activities, gene expression, growth differentiation, pathogen resistance, and apoptosis. Main pathways involved in the maintenance of the intracellular redox homeostasis are the TRX- and the GSH-dependent systems. These systems do not act in an individual and isolated manner, but they interact with other enzymatic and nonenzymatic components to prevent, repair, and regulate oxidative damages. In this way, we propose the scheme depicted in Figure 7.2 for reductive/oxidative equivalents flux between the main plant redox components described above. As the picture shows, different antioxidant and repair systems interact to exert specific functions related with redox homeostasis inside the cell. In this scenario, it is worth highlighting the position of the NADPH as a central donor supplying reducing equivalents for all the different reducing systems.

## 7.6 OXIDATIVE DAMAGE REPAIR SYSTEMS OPERATING IN PLANTS

All reactive species can modify different macromolecules to generate a cellular damage situation (Moskovitz 2005). For this reason, cells have many protective systems helping to eliminate or minimize injurious molecular species or to repair the oxidative damage caused on cellular components (Banerjee 2008). Particularly, oxidation of proteins can generate conformational changes and, in some cases, loss of function (Friguet 2006). The amino acids most susceptible to the oxidation are histidine, tryptophan, tyrosine, cysteine, and methionine; the latter two being the most sensitive (Moller et al. 2007). Systems for protein repair found in plants include SRXs and methionine sulfoxide reductases (Smirnoff 2005).

### 7.6.1 SULFIREDOXINS

As discussed in Section 7.5.2, typical 2CysPRX in eukaryotes are susceptible of hyperoxidation by excess of oxidizing substrate (Kiley and Storz 2004). As a result of this, the  $R-S_pOH$  (formed

during the catalytic cycle) generates the  $R-S_pO_2H$  (a more oxidized sulfur state by two electrons) (Rouhier and Jacquot 2002). The capacity of this hyperoxidation pathway in regulating PRX activity could provide cells the ability to maintain generation of local of  $H_2O_2$  under controlled levels. Consequently, the system operates maintaining concentrations of the peroxide in ranges compatible with its role in receptor-mediated, redox-dependent signaling processes (Rouhier et al. 2004). Another theory conjectures that PRX hyperoxidation leads to production of a high molecular mass PRX multimeric protein that exhibits chaperone activity to assist in cell recovery from oxidative stress (Aran et al. 2009, Hall et al. 2009). In plants, 2CysPRXs constitute the most abundant PRXs and are principally located in chloroplasts (Dietz et al. 2006). Lower oxidation states of cysteine (e.g., disulfides) are readily reversible; but higher oxidation states (such as  $R-S_pO_2H$ ) were once considered irreversible in a biological scenario (Moller et al. 2007). This point of view was revisited with the discovery of SRX, an enzyme that can reduce  $R-S_pO_2H$  back to  $R-S_pOH$ , in an ATP-dependent manner (Biteau et al. 2003, Chang et al. 2004).

Plant SRX proteins present high identity with orthologs from yeasts and humans, as they have the conserved signature sequence and residues essential for catalysis (Liu et al. 2006). Nevertheless, SRXs from plants possess a distinctive transit peptide directing them to the chloroplast. A study performed with SRX-GFP fusion protein indicated that this protein was targeted to the chloroplast in *Arabidopsis* mesophyll protoplast (Rey et al. 2007). Several experiments revealed that the expression of SRX genes occurred in both vegetative and reproductive organs and the highest transcript level was detected in leaves (Banerjee 2008). In addition, SRX transcript level is considerably augmented under oxidative stress, in parallel with enhanced transcription of 2CysPRX, which is essential in maintaining the chloroplast redox balance (Dietz et al. 2006, Rey et al. 2007).

SRX reduces hyperoxidized PRX in the presence of  $Mg^{2+}$  and ATP, transferring the phosphoryl group from the nucleotide to the PRX sulfinic acid. This generates a sulfinic phosphoryl ester that is the first step required for the activation of this species (Jonsson et al. 2009). The catalytic mechanism includes the nucleophilic attack on the sulfinic phosphoryl ester by the thiolate of the essential cysteine in SRX, thus producing the thiosulfinate linkage between the two proteins (Jonsson et al. 2008). Subsequently, the breakdown of the complex by reaction with another attacking thiolate generates a disulfide bridge in SRX (Roussel et al. 2008). It appears that TRX, and possibly GSH, can serve as reductants in the repairing process (Park et al. 2009, Roussel et al. 2009). On the other hand, numerous investigations show that SRX has differential reactivity toward diverse hyperoxidized PRX targets (Jonsson and Lowther 2007).

### 7.6.2 METHIONINE SULFOXIDE REDUCTASES

We analyzed before (see Section 7.3.2) a general view on the oxidation of sulfur-containing amino acids in proteins and the role of repairing enzymes such as MSRs. Plants have multiple forms of MSRA and MSRB, which are targeted to different cellular compartments (Tarrago et al. 2009). Multiple locations of MSRA and MSRB enzymes indicate that reduction of oxidized methionine residues in proteins takes place independently within the different subcellular locations (Rouhier et al. 2006, 2007). In addition, the overexpression of MSRB2 in *A. thaliana* transgenic plants generates enhanced tolerance to cellular oxidative damage during long nights (Bechtold et al. 2004, Romero et al. 2004).

Several studies indicate that MSRA and MSRB share a similar reaction mechanism (Boschi-Muller et al. 2008, Kauffmann et al. 2005), which proceeds in a series of steps. First, the catalytic cysteine thiolate (situated in the N-terminal part of MSRA and the C-terminal portion of MSRB) attacks the sulfoxide, releasing methionine and producing a sulfenic acid intermediate on the cysteine. Second, the sulfenic acid intermediate is attacked by the resolving cysteine generating an intramolecular disulfide bond. Finally, TRX or other electron donors, such as GRX or GSH, reduce the intramolecular disulfide, regenerating MSR (Tarrago et al. 2009). Most MSRB also contain a

single zinc atom that supports a structural role in these proteins (Kauffmann et al. 2005). In addition, some MSRB lack any resolving cysteines, suggesting that the sulfenic acid intermediate may be directly reduced by TRX or GSH (linking to GRX) (Vieira Dos Santos et al. 2007) or CDSP32 (Rey et al. 2005).

Recent works provided evidence for the existence of a mechanism by which plants perceive  $H_2O_2$  associated to methionine oxidation (Emes 2009). The data indicate that the chemical oxidation of methionine residues by  $H_2O_2$  at key hydrophobic positions within canonical phosphorylation motifs in numerous enzymes inhibits protein kinases binding. This inhibition of kinases (including the calcium-dependent protein kinase and AMP-activated protein kinase families) can be reversed by MSR *in vivo* (Hardin et al. 2009). The authors demonstrate that this mechanism is directly linked to oxidative signals by means of changes in protein phosphorylation, contributing to knowledge on perception of redox signaling in plants.

## 7.7 CONCLUDING REMARKS

Plants, as all aerobic organisms, take advantage of the redox potential of oxygen using it in metabolic pathways. Antioxidants and ROS/RNS/RSS are important interacting systems with different functions in higher plants, which ensure high redox flexibility to the organism. Antioxidants are not passive bystanders in this cross talk, instead they function as key signaling components that constitute a dynamic metabolic interface between cell stress perception and physiological responses (Scandalios 2005). Normal metabolic conditions produce ROS and RNS as by-products. To avoid undesirable effects by these species, plants have effective defense mechanisms, including antioxidant enzymes and free-radical scavengers. Under certain situations, like biotic or abiotic stress as well as the course of development, an induction of ROS and RNS synthesis takes place, that act as signaling molecules, incoming complex downstream effects on both primary and secondary metabolisms. Circumstances like this could result in different situations, the cell responds to the ROS/RNS signal making appropriate adjustments and returning to physiological conditions. Otherwise, ROS/RNS production exceeds the capacity of antioxidant systems, cells are not able to return to homeostasis, oxidative damage is overcome, and genetically programmed cell suicide events are triggered.

It is now well established that most cells can adapt to oxidative stress by altering global gene-expression patterns, including transcription and translation of genes encoding antioxidants as well as other metabolic enzymes, and/or by posttranslational changes operated on proteins that could modify key regulators of redox responses (Grant 2008). In plants,  $H_2O_2$  has been recognized as a second messenger for signals triggered by ROS, and advances have been gained in the understanding of metabolic changes operated in consequence. Also, the role of  $\cdot NO$  and the problem of RNS has been clearly evidenced. However, areas related with regulation of gene expression, modulation of enzymes activity, and coordination/redirectioning of metabolic fluxes require intensive research to reach a complete and comprehensive view of how higher plants maintain levels of oxidative species under control. The use of post-genomics tools, including proteomics and metabolomics, are becoming to be utilized in this field and are critical for advancements in integrative outlooks. The challenge is complex, but the finding of responses to the different open questions foresees relevant consequences. The latter is a critical prerequisite in the design and establishment of manageable procedures to improve plant productivity under different environmental scenarios.

## ACKNOWLEDGMENTS

Work in our laboratory was granted by ANPCyT, CONICET, and UNL. DGA and CVP are fellows whereas SAG and AAI are Members of the Researchers Staff from CONICET.

## 8.1 INTRODUCTION

Plants have evolved complex systems of defense against variable and often potentially damaging environmental conditions. These systems involve mechanisms to sense stresses and to generate and transduce appropriate stress signals, which result in modulation of transcription profiles, leading also to appropriate changes in growth and development. Character of the individual responses depends on the type of stress, its strength and duration, as well as on the physiological state of plant and its strategy to cope with the particular stress.

The growth and development of plants, as well as their responses to changing environmental conditions, are, at least partially, regulated by phytohormones. Two major groups of classical hormones may be recognized: “stress hormones,” including abscisic acid (ABA), ethylene, jasmonic acid (JA) and salicylic acid (SA) and “positive growth regulators,” such as auxins, cytokinins (CK), gibberellins (GA), and brassinosteroids (BR). The former group mediates activation of the defense pathways, whilst the latter ones promote cell division and growth, affecting plant vigor and stimulating plant development. The characteristic feature of “stress hormones” is inhibition of cell division, which is in accordance with the growth suppression occurring frequently under stress conditions, in order to allow the reallocation of limited resources to energy costly defense responses (Lopez et al., 2008). Prolonged stress stimulates change of carbon fluxes from the primary to secondary metabolic pathways, inducing a shift of available resources in favor of a synthesis of secondary products (Iriti and Faoro, 2009).

## 8.2 PLANT HORMONES

### 8.2.1 STRESS HORMONES

#### 8.2.1.1 Absciscic Acid

Absciscic acid (ABA) is the key hormone in the response to abiotic stresses associated with dehydration apart from drought, salinity, and cold stresses. ABA confers resistance to dehydration not only in the stress conditions, but also in specific developmental stages, namely, in seed desiccation.

ABA is a 15-carbon terpenoid, formed by cleavage of 40-carbon precursor, synthesized from isopentenyl diphosphate via plastid terpenoid pathway (Finkelstein, 2006). ABA is synthesized in almost all cells that contain plastids. The key regulatory enzyme is NCED (9-*cis*-epoxycarotenoid dioxygenase). ABA can be deactivated by oxidative degradation or glucoconjugation.

ABA mediates both fast responses (stomata closure) and long-term changes in the expression of many stress-associated genes. As stomata are the place of predominant water loss, precise regulation of their aperture is of high importance at the conditions of water deficit. Stomata closure is caused by loss of turgor of the guard cells by ion efflux.

The first signal sent by the roots exposed to water deficit is alkalization of xylem sap, which allows more ABA molecules to reach the guard cells. At the higher xylem pH, ABA, as a weak acid, occurs preferentially in non-dissociated form, which cannot diffuse across the plasma membranes of mesophyll cells. Thus, much more ABA molecules can reach the stomata cells. Later on, stimulation of ABA biosynthesis, hydrolysis of its glucoconjugates, as well as elevation of ABA transport from the roots take place. ABA signal transduction starts with its binding to PYR/PYL/RCAR receptors proteins, which enables interaction with protein phosphatase ABI1 (PP2C). The formation of this complex results in derepression of kinase SnRK2.6/OST1 and activation of anion channel SLAC1.

After ABA binding to receptor, signal transduction is activated. The network involves production of reactive oxygen species (ROS), NO, elevation of intracellular  $\text{Ca}^{2+}$ , and activation of ion channels (outward transport of  $\text{K}^+$  and  $\text{Cl}^-$ ). The second messengers were identified as sphingosine-1-phosphate, inositol 1,4,5-triphosphate, myo-inositol-hexaphosphate, cyclic ADP-ribose, and phosphatidic acid. Stimulation of ABA signaling results in the expression of transcription factors (MYB, MYC, ABI5), which stimulate expression of the stress-inducible genes. ABA up-regulates expression of LEA proteins, proteases, chaperonins, ion and water channels, antioxidant enzymes, and enzymes involved in metabolism of compatible solutes (Finkelstein, 2006). Apart from the direct effect on gene expression, ABA can affect many posttranscriptional modifications (e.g., formation of cap-binding complex, transfer of mRNAs to nuclear speckles, stimulation of mRNA degradation by microRNAs) (Shinozaki and Yamaguchi-Shinozaki, 2007).

Binding of ABA to receptor FCA (FLOWERING CONTROL LOCUS A, an RNA-binding protein), localized in the nucleus, enables accumulation of mRNA for FLC (repressor of flowering), which prevents transition from vegetative to reproductive phase (Hirayama and Shinozaki, 2007). Inhibition of this transition may positively affect plant tolerances to stresses (e.g., winter wheat cultivars lose their frost tolerance after the initiation generative development, i.e., flower induction).

The other ABA receptor, ABAR, is localized in chloroplasts. ABAR is a H subunit of Mg protoporphyrin IX chelatase, which plays a decisive role in plastid retrograde signaling, i.e., transfer of the signal from chloroplast to the nucleus, in order to coordinate the expression of photosynthetic genes during plant stress responses (Fernandez and Strand, 2008).

The ABA role in biotic stress responses is not straightforward. ABA-induced stomata closure may limit the pathogen entry into the cells. In later stages of infection, high ABA levels were found to have a rather negative effect, especially in the case of biotroph infection (Robert-Seilanianz

et al., 2007). Potential explanation might be antagonistic relationship among individual signaling pathways. It seems that response to abiotic stress has preference in plants, i.e., that strong stimulation of ABA signal transduction pathway (indicating exposure to severe abiotic stress) may be associated with the suppression of the defense pathways toward pathogens.

Increase of the ABA content or over-expression of transcription factor(s) from ABA signaling pathways was repeatedly reported to enhance tolerance to abiotic stresses. Pretreatment of rice with ABA enhanced its tolerance to lead (Zhao et al., 2009). Elevation of ABA content by over-expression of the gene for the key ABA biosynthetic enzyme (*SgNCEDI*) in tobacco enhanced its tolerance to drought and salt stress, which was associated with elevated content of  $H_2O_2$  and NO, as well as of antioxidant enzymes Cu/Zn superoxide dismutase (SOD), catalase, ascorbate peroxidase, and glutathione reductase (Zhang et al., 2009b). Over-expression of *AtMYB96* increased drought tolerance in Arabidopsis, reducing simultaneously lateral root growth (Seo et al., 2009).

### 8.2.1.2 Ethylene

Ethylene is a hormone involved in response to biotic as well as abiotic stresses, playing an important role in stimulation of the expression of defense genes, leaf and fruit abscission, and programmed cell death (PCD). Apart from stress functions, ethylene regulates fruit ripening and determines the onset of natural as well as drought-induced senescence (Young et al., 2004). Ethylene has a negative effect on the photosynthetic performance of leaves.

Ethylene is the only gaseous hormone. It is formed in most organs of higher plants. Its transport through the tissues is very fast and easy. The ethylene precursor is methionine, converted to S-adenosylmethionine. The rate-limiting step is the formation of 1-aminocyclopropane-1-carboxylic acid (ACC) by ACC synthase. Ethylene biosynthesis is stimulated by stress, certain physiological processes (e.g., ripening of climacteric fruits), or auxin.

Ethylene has a characteristic triple response on etiolated seedlings, i.e., inhibition of hypocotyl growth and its radial swelling, exaggerated curvature of the apical hook, and down-regulation of root growth (Ecker, 1995). Due to this specific response, a number of mutants were isolated, which allowed identifying components of ethylene signaling pathway. Ethylene receptors are associated with the membrane of endoplasmatic reticulum. In the absence of ethylene, they interact with CTR1 kinase, repressor of ethylene signaling (Kieber et al., 1993). Ethylene binding to receptors requires a copper cofactor provided by copper transporter RAN1 (Hirayama et al., 1999). After ethylene binding, CTR1 is released from the complex with receptors, which results in the loss of its activity. Function of at least one ethylene receptor (ETR1) is regulated by another membrane protein RTE1/GR. Ethylene signal is transferred by phosphorelay to transmembrane protein EIN2 (Li et al., 2009) and then to transcription factors EIN3 and EIL1, which results in increase of their stability (Li and Guo, 2007). The strength of the signal is regulated by two F-box proteins EBF1 and EBF2, which control degradation of EIN3 and EIL1 by proteasome (Kendrick and Chang, 2008). As transcription of EBF2 is up-regulated by ethylene, this protein represents a negative feedback loop. EIN3 and EIL1 activate expression of a number of ethylene-induced genes, e.g., transcription factor ERF1, which converges ethylene and JA signaling pathway, or ERF3, involved in signaling pathway of ABA, SA, and JA.

Stimulation of ethylene production was found in drought as well as in flooding, cold, heat stress, salt, ozone, infection (especially with necrotrophs), and mechanical wounding. Stimulation of ACC synthesis and subsequently of ethylene was found in drought, when ethylene accelerated the senescence of the oldest leaves (Apelbaum and Yang, 1981). Increase of transcription of genes involved in ethylene biosynthesis was detected after flooding (Komatsu et al., 2009). It is interesting that ethylene production was stimulated after waterlogging in both susceptible and tolerant *Chrysanthemum* cultivars; however, ethylene peak occurred 2 days earlier and was 3 times higher in tolerant line. Simultaneously, antioxidant enzymes (SOD, ascorbate peroxidase and catalase)

were stimulated (Yin et al., 2009). Ethylene increases the tolerance to salinity stress by down-regulation of the growth via stabilization of DELLA proteins (Li and Guo, 2007).

Ethylene regulates entry into several types of PCD (Young et al., 2004). PCD was observed after ozone application, high light stress or wounding. Ethylene-induced PCD is involved in aerenchyma formation (Trobacher, 2009). PCD stimulated by ethylene is an important component of the hypersensitive response (HR) to pathogen infection, i.e., for the stimulation of the defense not only at the place of infection, but also at the distant tissues. Coordinated effect of ethylene and JA is necessary for initiation of the HR to necrotroph infection. Necrotrophs are pathogens that do not need living plant cells for their growth and multiplication. The other group of pathogens—biotrophs—require and utilize living plant cells for their nutrition.

Ethylene interacts with SA during HR to biotrophic pathogens (Mur et al., 2009). The first transient peak of ethylene was detected 1–4 h after inoculation with HR-eliciting strain. The second, avirulence-dependent rise of ethylene was found after 6 h (only in HR-eliciting strains). Oxidative stress or SA initiated monophasic ethylene generation, while NO was necessary for the biphasic pattern. Also, the response to ozone exhibited biphasic regulation of ethylene formation. Ozone application resulted in rapid (within 1 h) up-regulation of the expression of ACC synthase gene (*ACS6*), ACC oxidase genes (*ACO1*, *ACO3*) as well as of *ETR1* and *ETR2* (receptors) in tomato plants (Moeder et al., 2002). This stimulation was only transient, down-regulated by negative feedback. Later on, the second stimulatory phase occurred. The expression pattern of ethylene co-localized with increase of  $H_2O_2$  after 7 h and necrotic lesions (indication of cell death) after 24 h. In tobacco, ozone application was reported to induce within 90 min peak of NO, which caused rapid  $H_2O_2$  accumulation, followed by an increase in ethylene levels (which might correspond to the second ethylene phase) (Pasqualini et al., 2009). Also Wang et al. (2009) concluded in their study of salt stress response that ethylene was a downstream signal molecule in NO action. Both substances were found to be involved in stimulation of plasma membrane  $H^+$ -ATPase activity involved in control of ion homeostasis (including  $Na^+/K^+$  ratio).

Stimulation of ROS and ethylene signaling resulting in PCD was reported after high light stress (excess excitation energy stress) (Muhlenbock et al., 2008). Dose-dependent elevation of ethylene was also detected at irradiation with UV-B and UV-C (Katerova et al., 2009). Ethylene elevation, stimulation of caspase-like proteases, and subsequent PCD were detected after treatment with cadmium (Iakimova et al., 2009). Similar effect was also exhibited by mercury (Ge et al., 2009). Ethylene plays an important role in leaf and petal abscission, when sensitivity to ethylene is increased only in cells of abscission zone (after down-regulation of auxin transport from the leaf). Ethylene then induces expression of enzymes involved in cell-wall loosening (e.g., cellulase). Leaf abscission is an important mechanism to decrease water loss by diminishing the leaf surface.

Ethylene exhibits an intensive cross-talk with other hormones, predominantly with JA. Antagonistic relationship between ethylene and ABA signaling seems to be the reason for reduced sensitivity of stomata closure to ABA after exposure to ozone, which is associated with ethylene elevation (Wilkinson and Davies, 2009).

Ethylene levels may be increased by incubation in ethylene atmosphere, by application of ethrel, or simply by an incubation with ripe climacteric fruits (e.g., bananas or apples), which emanate ethylene. Over-expression of genes for ethylene biosynthetic enzymes was reported to increase stress tolerance. Also, over-expression of transcription factor *GmERF3* increased tolerance to drought, salt, as well as to diseases (Zhang et al., 2009a).

Down-regulation of ethylene levels may be achieved by inhibition of biosynthetic enzymes (with aminooxyacetic acid or aminoethoxyvinylglycine), ethylene signaling by  $Ag^+$ , which binds to receptors instead of Cu. Antisense expression of genes for ACC synthase and ACC oxidase was found to reduce ethylene evolution after wounding. Down-regulation of ethylene production may improve regeneration of some *in vitro* cultures, preventing accumulation of ethylene to growth inhibitory levels in closed space above the explant. Manipulation of ethylene levels is widely used in controlled fruit ripening and prolongation of fruit shelf life. Sometimes, both stress response and modulation of the developmental process may affect each other. For example, increase of ethylene biosynthesis

in avocado fruits by in-orchard chilling stress was found to speed up fruit ripening, shortening substantially the shelf life of harvested fruits (Hershkovitz et al., 2009).

### 8.2.1.3 Jasmonic Acid

Jasmonic acid (JA) mediates resistance to necrotrophic pathogens and wounding (e.g., by pests). JA is involved in local PCD, which restricts pathogen invasion as well as hypersensitive response. JA was reported to play an important role in the defense to ozone and salinity stresses. JA, as well as ABA, down-regulates cell division, inhibiting cell cycle progression. When applied before G<sub>1</sub>/S transition, JA or ABA prevented DNA replication, keeping the cells in G<sub>1</sub> phase. JA also prevented mitosis, suppressing G<sub>2</sub>/M transition by reduction of histone H1 kinase activity of kinases associated with p13<sup>suc1</sup> protein (Swiatek et al., 2002). JA also exhibits negative effects on photosynthetic performance of the leaves, which allows avoiding potential damage of both photosystems under stress conditions. JA has also important functions in the regulation of plant development, e.g., inhibition of root growth, potato tuberization, fruit ripening or pollen viability, and stimulation of plant senescence (Chico et al., 2008).

JA belongs to a family of oxylipins. Jasmonate biosynthesis starts in plastids, where membrane lipids are cleaved by phospholipases to release  $\alpha$ -linolenic acid. Phospholipase D (PLD) activity during the wounding response was found restricted to the ruptured cells (Bargmann et al., 2009). Linolenic acid is oxidized by lipoxygenase (LOX) to 13(S)-hydroperoxylinolenic acid, which is via 12,13(S)-epoxylinolenic acid further oxidized to 12-oxo-phytodienoic acid (OPDA). After OPDA transport to peroxisomes, JA is produced by repeated  $\beta$ -oxidation.

Synthesis of JA is stimulated by systemin, a proline-rich peptide comprising of 18 amino acid residues. Systemin itself is released after wounding from prosystemin (200 amino acid residues) in parenchyma cells of vascular bundles (Hause et al., 2003). Induced JA stimulates signal transduction in wounded leaves. Simultaneously, JA promotes formation of systemin. This positive feedback loop allows amplification of the signal after wounding or infection.

JA can be metabolized to tuberonic acid (12-hydroxy derivative of epi-JA), which is (as well as its sulfate) a deactivation product. The volatile derivative of JA, its methylester, is also considered as the active form. It may serve as a mobile signal exerting communication among attacked and non-harmed plants. JA forms conjugates with glucose and amino acids, especially with isoleucine (Ile). The key enzyme for this conjugate formation is JAR1. JA-Ile is physiologically active in the signal transduction.

JA-Ile conjugate was found to mediate (like a glue) interaction between JA receptor COI1 (F-box protein of an SCF-type E3-ubiquitin ligase) and JA repressors JAZ (jasmonate ZIM-domain proteins). In *Arabidopsis*, 12 JAZ proteins were found with different tissues and pathway specificity. JAZ binding to COI1 initiates its degradation by proteasome, which releases expression of transcription factors, especially MYC2 (bHLHzip-type), but also ERF1, ERF2, ERF4, MYB21, MYB24, WRKY70, and WRKY18 (Chico et al., 2008). MYC2 positively regulates resistance to insect and herbivory, tolerance to oxidative stress, and flavonoid synthesis. It negatively regulates tryptophan metabolism (Dombrecht et al., 2007). Apart from the stimulation of the defense genes, MYC2 transcription factor also up-regulates expression of JAZ. This negative feedback loop allows precise regulation of the strength of the signal and its effective “switch off” (Chini et al., 2007).

JA-induced genes include proteinase inhibitors, enzymes of flavonoid biosynthesis (chalcon synthase, phenylalanine ammonia lyase, and polyphenol oxidase), sesquiterpenoid biogenesis, and antifungal protein (thionin and osmotin) production (Vasyukova and Ozeretskovskaya, 2009). Expression of genes for proteinase inhibitors was recorded 1–2 h after mechanical wounding or insect attack (Zhao et al., 2003). Proteinase inhibitors inactivate nutrient digestion enzymes in insects. Their knockdown resulted in much faster consumption of leaves by caterpillars. Plants can distinguish between mechanical wounding and insect-induced damage and adjust their defense.

Apart from the huge transcriptomic changes, JA responses involve modulation of ion fluxes across the plasma membrane, generation of reactive oxygen species (ROS) and NO, deposition of callose, activation of calcium-dependent and MAP kinases (Lopez et al., 2008).

Wounding was reported to induce two peaks of JA in wounded leaves and stalks, but only one peak in systemic leaves (Yang et al., 2009). LOX activity (as well as the protein) was induced in the later phase. Wound-induced JA originated in wounded leaves from its biosynthesis and conversion from its conjugates, while in systemic leaves it resulted from transport and biosynthesis via LOX pathway.

Rapid accumulation of JA-Ile (in less than 5 min) was found after wounding in Arabidopsis leaves, distal to the wound site (Koo et al., 2009). Wound-induced systemic production of JA-Ile required JA biosynthetic enzymes (namely, OPDA reductase 3) in undamaged responding leaves. Induced synthesis of JA-Ile correlated with a rapid decline of OPDA, which indicated that transmitted signal triggered systemic synthesis of JA, which upon conversion to JA-Ile by JAR1 activated the expression of early response genes.

#### 8.2.1.4 Salicylic Acid

Salicylic acid (SA) is the key hormone in defense to biotrophic pathogens. Protective properties of SA and of several its derivatives have been recognized for many centuries in human medicine. Hippocrates in the fifth century B.C. recommended bark from *Salix*, natural source of SA, for treatment of cold or fever. Nowadays, a derivative of SA, acetylsalicylic acid, belongs to abundantly used medicines. As a plant hormone, SA governs resistance to biotrophs. SA mediates both the immediate defense against infection and systemic acquired resistance (SAR), which provides a long-lasting protection from further infections by a broad range of biotrophic, hemibiotrophic, and necrotrophic pathogens (Grant and Lamb, 2006). SA suppresses auxin and ABA signaling, which allows diminishing of the availability of nutrients for pathogens as well as relocation of plant resources toward activation of defense compounds (Lopez et al., 2008). SA may enhance tolerance to abiotic stresses by stimulation of antioxidative capacity (Horvath et al., 2007).

SA is an *o*-hydroxyderivative of benzoic acid. It is synthesized in plants from chorismic acid either by isochorismate synthase and isochorismate pyruvate lyase or by phenylalanine ammonia lyase. SA can be reversibly converted into its methylester. Down-regulation of SA levels is achieved by SA decarboxylation.

Crucial positive component of SA signal transduction pathway is NPR1 protein (nonexpressor of pathogenesis-related genes1). Non-induced form of NPR1 is an oligomer. Upon SAR induction, NPR1 is reduced and transported in monomeric form to nucleus, where it activates gene expression (Mou et al., 2003). SA signaling pathway has NPR1-dependent and NPR1-independent branches (stimulation of 193 and 24 genes in Arabidopsis, respectively, Despres et al., 2000). Immediately downstream of NPR1 is activation of the subclass II of TGA transcription factors, TGA2, TGA5, and TGA6 (Zhang et al., 2003). Other primary targets of NPR1 are genes coding ER proteins of secretory machinery and WRKY transcription factors. SA was found to induce activity of phospholipase D (within 45 min); this stimulation is upstream of induction of WRKY38 (Krinke et al., 2009). SA-activated transcription factors include these groups: NAM, ERF/AP2, and MYB. Another early response gene is phosphatidylinositol 4-kinase (Krinke et al., 2007).

Some of the best characterized NPR1-dependent genes are coding pathogenesis-related proteins (PR-proteins), especially PR-1, PR-2, and PR-5 (Srinivasan et al., 2009; Blanco et al., 2009). PR-proteins represent important components of plant defense against pathogens. Recently, 17 families of PR-proteins have been classified. Their expression and accumulation is very specific, precisely associated with the type of pathogen, type of plant cells, and biosynthesis and activation of signaling compounds, i.e., SA, JA, and/or ethylene (Byczkowski et al., 2009). Many PR proteins occur in plants constitutively (although at low concentration). Some of them are specific for certain developmental stages or for specific tissues.

SA-binding protein SABP2 was identified as methyl salicylate esterase. This enzyme is inhibited by its product—SA (Forouhar et al., 2005). SABP2 is required for SAR signal perception in systemic tissue (Park et al., 2007a). The data indicate that MeSA is a long-distance signal in SAR, produced from SA by SA methyltransferase in primary infected leaves and released back to SA in the systemic ones. In *Arabidopsis*, five genes for MeSA-esterases were recently found (Vlot et al., 2008). Three of them, AtMES1, 7, and 9 were found transcriptionally up-regulated during infection with avirulent strain of *Pseudomonas syringae*.

SA plays additional roles in defense and acclimation responses to stresses, such as intracellular stress signaling, improvement of pathogen recognition, and promotion of metabolic changes (Blanco et al., 2009). Upon infection, levels of SA and its glucosylconjugate increase, both in infected and systemic leaves. SA accumulation is induced by  $H_2O_2$ , suggesting a link between the oxidative burst observed during hypersensitive reaction and induction of SA-mediated signal transduction (Summermatter et al., 1995). Positive feedback interaction between SA and ROS seems to be associated with PCD (Overmyer et al., 2003). SA is also involved in the control of cellular redox balance at the onset of SAR.

SA role in various abiotic stress responses seems to be based on its ability to stimulate the activity antioxidant system, which improves integrity of cellular membranes and facilitates sustainment of photosynthesis and of general metabolism (Farooq et al., 2009). SA activates genes coding for detoxifying or antioxidant enzymes. The first characterized SA-binding protein was identified as catalase. Another SA-binding protein, SABP3, was found in the chloroplast stroma (Slaymaker et al., 2002). It was identified as carbonic anhydrase with antioxidant activity. SA pretreatment was reported to increase the tolerance to cold stress, as well as to heavy metals by stimulation of the antioxidant enzymes ascorbate peroxidase and Cu/Zn superoxide dismutase (Horvath et al., 2002; Krantev et al., 2008). SA was also reported to enhance activity of glutathion S-transferases and glucosyltransferases (Blanco et al., 2009).

SA was reported to be active also in the defense against rice blast (Bailey et al., 2009), in spite of the fact that JA pathway, together with ethylene, mediates rice defense gene expression. It was found that SA acts here as a constitutive antioxidant, protecting rice from the pathogen-induced oxidative damage.

Plants and pathogens have continuously confronted each other during evolution in a battle for growth and survival (Lopez et al., 2008). The antagonistic relationship between SA and JA signaling pathway has been utilized by pathogen *Pseudomonas syringae*, which produces JA-Ile analogue, phytotoxin coronatine. This phytotoxin is able to stimulate JA signaling pathway, which results in the suppression of the SA pathway (Brooks et al., 2005). It is interesting that coronatine also facilitates bacterial invasion by repression of ABA-mediated stomata closure (Melotto et al., 2006).

Activation of plant defense signaling pathways depends on the pathogen lifestyle and its mode of infection. Some pathogenic fungi secrete mannitol into the apoplast to suppress ROS-mediated host defense. Part of SA-induced defense is secretion of symplastic plant enzyme mannitol dehydrogenase into the apoplast, where it converts mannitol to mannose (Cheng et al., 2009).

Exposure to stress (nonlethal) usually increases tolerance to subsequent stresses, mainly due to the maintenance of the concentrations of certain components of defense pathways up-regulated above their basal levels (for certain period), which makes the response to another stress (even of different kind) faster and more efficient. On the contrary, simultaneous exposure to different stresses has usually a negative impact, as different signaling pathways affect each other in an antagonistic way (as mentioned above in case of ABA and JA or SA signaling). Thus, exogenous SA at low concentration (less than 0.25 mM) enhanced drought tolerance of barley leaves, elevating the expression of dehydrin gene, as well as the level of the corresponding protein, decreasing the electron leakage and malondialdehyde and hydrogen peroxide content (Sun et al., 2009). High SA concentration (above 0.5 mM) had negative effects, suppressing the accumulation of dehydrin proteins and aggravating the oxidative damage.

Modulation of SA levels was used for the study of the mode of action of this hormone. Down-regulation of SA levels was achieved by over-expression of the gene for SA decarboxylase.

Stimulation of SA signaling by over-expression of specific signaling components was reported to enhance tolerance to different stresses. For example, over-expression of *NPR-1* had positive effect on SA-mediated response to fungal and bacterial pathogens, but negative effect on the tolerance to dehydration and salt stresses as well as viral infection (Quilis et al., 2008).

## 8.2.2 POSITIVE GROWTH REGULATORS

### 8.2.2.1 Auxin

Auxin is a crucial hormone for regulation of plant growth, orchestrating many developmental processes, especially embryogenesis, differentiation of vascular tissues, and lateral root initiation (Woodward and Bartel, 2005). Auxin is indispensable for cell division and elongation. It exhibits its multiple physiological effects, including apical dominance, stimulation of root growth, tropic responses, and prevention of abscission.

The most extensively studied endogenous auxin is indole-3-acetic acid (IAA). IAA is synthesized by several tryptophan-dependent and independent pathways. IAA is formed primarily in shoot and root apices, but also in leaves (especially, the young ones), cotyledons, and roots. There are two main pools of auxin in the cells: the cytosol and chloroplasts. IAA can be reversibly converted to indole-3-butyric acid (IBA). The levels of free IAA are regulated by conjugation with sugars, amino acids, and peptides. Levels of IAA are also down-regulated by its degradation, compartmentation, and polar auxin transport. Auxin polar transport represents an important mechanism in its mode of action. It is regulated predominantly by asymmetrical localization of auxin efflux proteins, PINs, in the cells (Zazimalova et al., 2007).

Auxin signaling pathway involves formation of a complex between receptors TIR and repressors of Aux/IAA family. Auxin mediates (like a glue) their binding, which stimulates degradation of the repressor molecules by proteasome. After repressor removal, positive ARF proteins can stimulate expression of auxin-responsive genes (Tiwarei et al., 2004). The early auxin-responsive genes include transcription factors, genes involved in stress adaptation, and intercellular signaling. Auxin rapidly and transiently induces accumulation of at least three families of transcripts: SMALL AUXIN-UP RNAs (SAURs), GH3-related transcripts (coding enzymes involved in IAA-amino acid conjugation), and those coding repressor AUXIN/INDOLE-3-ACETIC ACID (Aux/IAA) proteins (Woodward and Bartel, 2005). Stimulation of the expression of Aux/IAA genes by auxin (resulting in accumulation of new repressors) ensures transient character of auxin signal.

As mentioned above, IAA is a strong positive regulator of cell division and growth. Its high content in shoot apex and young leaves coincides with relatively high growth rate. Many abiotic stresses are associated with the suppression of the shoot growth, which is in good correlation with the decrease in free IAA content in apex and upper leaves observed, e.g., in drought-stressed tobacco (Havlova et al., 2008). Modulation of free IAA content involves stimulation of *GH3* genes for auxin-conjugating enzymes. Park et al. (2007b) suggested that GH3-mediated down-regulation of IAA levels, resulting in growth suppression, directs reallocation of metabolic resources to defense pathways. Also cold stress, both sudden and with previous acclimation, have been associated with down-regulation of auxin levels by strong increase of GH3-like proteins (Meng et al., 2008). Auxin signaling was found down-regulated, e.g., by cold-inducible microRNAs (Zhou et al., 2008).

Very prominent feature of abiotic stress responses is stimulation of IAA accumulation in roots. Several reports (Ribaut and Pilet, 1994; Xin et al., 1997; Havlova et al., 2008) described significant increase of IAA in roots of drought-stressed plants. Auxin accumulation in roots might allow maintenance of the root growth resulting in the elevation of the root/shoot biomass ratio. Simultaneous elevation of ABA (Seo et al., 2009) and cytokinins (Havlova et al., 2008) seemed to prevent lateral root formation. Initiation of lateral roots requires local auxin maxima. Drought-enhanced ABA stimulated expression of MYB96 transcription factor, which down-regulated auxin levels via induction of *GH3* genes at the sites of potential lateral roots initiation (Seo et al., 2009). The resulting effect is stimulation of the primary root growth, which allows the plant to

reach deeper soil levels obtaining access to underground water. Relatively high CK levels in stressed roots might also contribute to this phenomenon.

Similar changes as drought, i.e., strong down-regulation of IAA in the leaves and accumulation in roots, were imposed by salinity (100 mM NaCl, 3 weeks) (Albacete et al., 2008).

Apart from its morphological effects, accumulation of auxin in stressed roots may have protective functions. Auxin application was found to induce Cu/Zn SOD and catalase transcripts in the distal root zone and peroxidases in the whole root. Simultaneously, levels of H<sub>2</sub>O<sub>2</sub> were diminished (Tyburski et al., 2009). The positive effects of auxin on antioxidant system may be involved also in the response to heavy metal stresses. Exposure to arsenic induced in the stress-tolerant variety of *Brassica juncea* L. fast (within 6 h) transcriptome changes, which included up-regulation of auxin and JA biosynthesis and down-regulation of ethylene biosynthesis and CK-responsive genes. This coordinated hormonal response was not found in the sensitive variety (Srivastava et al., 2009). Stimulation of the expression of auxin-responsive protein (SdARP) upon mercury stress was observed in the heavy metal hyperaccumulator *Sesbania drummondii* (Venkatachalam et al., 2009). Also, the response to aluminum stress involved up-regulation of auxin-responsive genes, together with genes for peroxidases, chitinases, and GSTs (Goodwin and Sutter, 2009). Genes involved in maintenance of chloroplast structure and photosynthesis were down-regulated. Toxic levels of aluminum were found to suppress root growth, mainly by blocking auxin transport via inhibition of the transport of PIN2 containing vesicles from plasma membrane to endosomes (Hong et al., 2009).

IAA plays an important role in delay of abscission. Auxin flow from the (stress-induced) senescing leaves is necessary to diminish the sensitivity of cells from abscission zone to ethylene. After auxin flow cessation, the ethylene sensitivity increases and abscission starts. Delay in abscission might contribute to relocation of nutrients from senescing leaves before their final death. Increase in free auxin levels in senescing leaves by nitrilase 2, an enzyme mediating the synthesis of IAA from indole-3-acetonitrile, was described by Quirino et al. (1999).

Function of auxin in biotic stress response depends on the type of invading pathogen. Some biotrophs enhance nutrient and water supply from the host by modulation of plant-hormone production and/or signaling. They can produce hormones themselves, as a component of their invading strategy (Lopez et al., 2008). For example, *Moniliophthora perniciosa*, which colonizes apoplast as biotroph pathogen causing “Witch’s broom” disease, is able to produce both auxin and gibberellins (Mondego et al., 2008). Plants defend to biotrophs by down-regulation of auxin signaling. Elevation of the content of miR393, involved in repression of auxin signaling, contributed to resistance against *Agrobacterium tumefaciens* (Pruss et al., 2008).

Some bacteria, which produce auxin, can be, however, beneficial, for plants. IAA-overproducing strain of *Sinorhizobium meliloti* improved the growth of *Medicago truncatula* by elevation of the IAA content in roots and nodules (Bianco and Defez, 2009). Nodulated plants had enhanced salt tolerance, which coincided with stimulation of the activity of antioxidant enzymes (SOD, peroxidases, glutathion reductase and ascorbate peroxidase).

### 8.2.2.2 Gibberellins

Gibberellins (GAs) were first isolated from a filtrate of pathogenic fungus *Gibberella fujikuroi*, which caused tall growth of rice plants, reducing their seed production. Later on, they were identified also as plant hormones. GAs regulate numerous developmental processes, especially seed germination, stem elongation (of rosette plants), leaf expansion, and stimulation of flowering. They inhibit nodulation and tuberization. Until now, more than 136 GAs have been found, but only few are physiologically active (GA<sub>4</sub> and GA<sub>1</sub>).

GAs are diterpenes synthesized from geranylgeranyl diphosphate. The key biosynthetic enzymes are GA 20-oxidase (GA20ox) and GA 3-oxidase (GA3ox). GA inactivation is achieved either by their 2-hydroxylation by GA 2-oxidase or by GA glucosylation. Recently, other GA deactivation enzymes were reported: cytochrome P450 monooxygenase and GA methyltransferase (Zhu et al., 2006; Varbanova et al., 2007).

GA signaling pathway is strongly down-regulated by repressors DELLA proteins (Zentella et al., 2007), which require for their full activation function of O-linked *N*-acetylglucosamine transferase SPY (SPINDLY, Maymon et al., 2009). Binding of GA to soluble receptor GID1 enables its interaction with DELLA proteins and targeting repressors to 26S proteasome degradation. Removal of repressors allows stimulation of the expression of MYB transcription factors and subsequent GA responses, e.g., up-regulation of  $\alpha$ -amylase genes.

It seems that tolerance to abiotic stresses coincides with down-regulation of active GA levels or suppression of sensitivity to GAs (e.g., at heat stress, Sarkar et al., 2004). Repression of *GA3ox1* gene was found under strong salinity stress (Kim et al., 2008). UV-B exposure was found to decrease endogenous GA levels via induction of genes involved in GA deactivation: *GA2ox2* and *GA2ox8* (Ulm et al., 2004). Salinity was reported to result in stimulation of the expression of 6 genes for GA 2-oxidases (Magome et al., 2008). Expression of *GA2ox7* was in Arabidopsis up-regulated by DDF1 (dwarf ABD delayed flowering 1), an AP2 transcription factor of the DREB1/CBF subfamily. Under high salinity, DDF1 not only affected GA synthesis, but also GA signaling by up-regulation of DELLA protein RGL3 (Kim et al., 2008). Stabilization of DELLA proteins coincides with GA down-regulation and results in stimulation of the expression of genes for ROS-detoxifying enzymes (Achard et al., 2008a). DELLA proteins contribute significantly to cold acclimation and freezing tolerance (Achard et al., 2008b). They restrain cell production by enhancing levels of the cell cycle inhibitors Kip-related protein 2 (KRP2) and SIAMESE (SIM) (Achard et al., 2009).

GAs also negatively regulate accumulation of transcription factor GhDREB1, which is induced by low temperature and salt stress. Tobacco plants over-expressing *GhDREB1* displayed stronger chilling tolerance, maintaining higher net photosynthesis rate and proline content than WT (Shan et al., 2007). Under optimal conditions, they, however, display retarded growth and delayed flowering.

When the effect of osmotic stress (achieved by 12% PEG application) on hormone pools was followed, down-regulation of GAs was accompanied by decrease of CKs, while transient stimulation was observed in case of IAA and high up-regulation in case of ABA (Wang et al., 2008). It is interesting that growth of roots was much less retarded than that of shoots.

Negative effect of heavy metals (Hg, Pb) on flowering time could be partially overcome by exogenous GA<sub>3</sub> application (Chaudhry and Khan, 2006).

GAs have strong stimulatory effect on seed germination. Their exogenous application was repeatedly found to promote seed germination even under unfavorable stress conditions (Alonso-Ramirez et al., 2009). Exogenous GA in combination with CKs enhanced longevity of flowers and leaves of pot tulips (Kim and Miller, 2009).

### 8.2.2.3 Brassinosteroids

Brassinosteroids (BR) are polyhydroxylated steroids, which stimulate growth of both shoots and roots, positively affect cell elongation (in synergism with auxins), cell division (stimulating cyclin D3, similarly to CKs), lateral root growth, promote xylem differentiation, seed germination, pollen tube growth, photomorphogenesis and, especially, stress tolerance (Chory, 2006). BR strongly enhance tolerance to various stresses: cold, heat, salt, drought, high light, heavy metals and viral, bacterial, and fungal infections (Nakashita et al., 2003).

BRs are synthesized via terpenoid pathway from the same precursor as ABA, CKs, and GAs (isopentenyl diphosphate). Two farnesyl diphosphate molecules form squalene, which may cyclise to cycloartenol. Important intermediate of BR synthesis is campesterol, metabolized in several steps to bioactive castasterone and the most active BR brassinolide. BR are deactivated by 26-hydroxylation. The highest level of BRs is in the apical shoot.

BR signaling pathway involves binding of BR to plasma membrane receptor BRI1, which subsequently interacts with coreceptor BAK1 (BRI1-associated receptor kinase 1) (Li and Nam, 2002). BR signal transduction results in deactivation of the repressor kinase BIN2. In the absence of BR, BIN2 phosphorylates transcription factors BES1 (bri1-EMS-suppressor1) and BZR1 (brassinazole-resistant 1), which targets them to proteasome degradation (Belkhadir and Chory, 2006). In the

presence of BR, BES1 and BZR1 are dephosphorylated with Ser/Thre phosphatase BSU1, which enhances their activity. The active BES1 is associated with another transcription factor BIM1 (BES1-interacting Myc-like 1) and binds to the BR-response element in promoters of BR-inducible genes, stimulating their expression. BZR1 binds to promoters of BR biosynthetic genes and represses them. This gene suppression represents negative feedback loop. BRs were reported to induce the expression of heat shock proteins (HSP83, HSP70), heat shock factors (HSF3), and oxidative stress-related genes—GST, ATPA2 and ATPA24a (Goda et al., 2002; Mussig et al., 2002). BR-induced transcription factors are, e.g., WRKY6, CBF/DREB, MYB (e.g., AtMYB30), and MYC. Further BR-induced genes include those coding MAPK1 and MAPK3, phenylalanine ammonia lyase, catalase, ascorbate peroxidase, SOD and glutathione reductase, as well as PR-1 (Xia et al., 2009).

Model for BR induction of stress tolerance was recently presented by Xia et al. (2009). Perception of BR by receptors results in the activation of plasma membrane-bound NADPH oxidase, which may release  $H_2O_2$  into apoplast. Hydrogen peroxide then functions as a signal molecule activating stress response pathways.  $H_2O_2$  levels were found elevated 3 h after BR application and returned to basal level after 3 days.

The activated pathways involve MAPK and stimulation of antioxidant system. BR action was found unrelated to SA signal transduction pathway or to SAR (Robert-Seilanianantz et al., 2007).

Exogenous application of BRs was found to diminish significantly adverse effects of various stresses. Foliar spray of BR was reported to increase drought tolerance in rice, improving net  $CO_2$  assimilation, water use efficiency, leaf water status, membrane properties, free proline content, anthocyanins, and soluble phenolics (Farooq et al., 2009). Uncontrolled increase of  $H_2O_2$  and membrane lipid peroxidation was diminished. Pretreatment with 24-epibrassinolide significantly reduced severity of *Fusarium wilt* infection, improving plant growth (Ding et al., 2009). BRs were reported to increase the yield of bean seeds or lettuce biomass. Their positive effects may be recognized mainly under stress; under optimal conditions, they show only little effect (Ikekawa and Zhao, 1991).

#### 8.2.2.4 Cytokinins

Cytokinins (CKs) were defined as substances stimulating (in the presence of auxin) cell division (cytokinesis) in tissue cultures (Miller et al., 1955). They are indispensable for cell cycle  $G_2/M$  transition (Laureys et al., 1998; Dobrev et al., 2002). They also positively affect  $G_1/S$  transition, stimulating the level of CycD3, which can be, however, increased also by other substances, e.g., sucrose (Riou-Khamlichi et al., 1999). CKs exhibit multiple physiological functions: stimulate differentiation of chloroplasts and positively affect photosynthesis by stabilization of the structure and function of the photosynthetic machinery (Chernyadev, 2009), delay senescence, open stomata, enhance the sink strength (Skoog et al., 1965), and stimulate branching. CKs play a critical role in balancing acquisition and distribution of macronutrients (Hirose et al., 2008). This effect might be associated with CK stimulation of invertase activity (Roitsch and Ehness, 2000).

Natural CKs are adenine derivatives with either isoprenoid or aromatic side chain. The key enzymes of isoprenoid CK biosynthesis are isopentenyltransferases (IPT), which catalyze reaction of isopentenyl diphosphate with ATP (or ADP) (Takei et al., 2001; Kakimoto, 2001; Kamada-Nobusada and Sakakibara, 2009). Down-regulation of CK levels is governed by cytokinin oxidases/dehydrogenases, which cleave the side chain. The other important mechanisms of suppression of CK activity are their glycosylation, irreversible (at the adenine ring in position N7- or N9-) or reversible (O-glucosylation of the side chain or, quite rare, N3-glucosylation, Mok and Mok, 2001). The highest CK content is in root apex. High CK concentrations can be detected at lateral root tips and in shoot apex. CKs are also present in the stem and in leaves (in inverse correlation with the leaf age), especially along the vasculature.

Three CK receptors (AHK2, 3, and 4) differ in their specificity as well as affinity to individual CK bases or, to a lower extent, to ribosides (Spichal et al., 2004; Mok et al., 2005). Structural variation of

the side chain mediates different biological messages, *trans*-zeatin being predominant in regulation of cell division (Hirose et al., 2008). CK signal is transferred by phosphorelay via AHP proteins to type-B response regulators, and by transcription factors which stimulate CK early response genes or negative type-A response regulators, important for “switching off” of the signal. The signal is modulated also by transcription factors, CRFs (Rashotte et al., 2006; Argueso et al., 2009).

Endogenous CK levels are strictly regulated during the abiotic stress responses, both in time- and tissue-specific manner. CKs have an important role in drought response, ensuring preferential protection of shoot apex by elevation of the sink-source polarization of plants in favor of younger leaves (Cowan et al., 2005). The establishment of gradient of active CKs in favor of upper tobacco leaves was found already in mild stress, when it was promoted by elevation of active CKs in upper leaves (Havlova et al., 2008). During drought stress progression, when the levels of active CKs in shoots substantially decreased, their gradient was maintained by stimulation of the activity of cytokinin oxidases/dehydrogenase in lower leaves.

CK levels were much less affected in drought-stressed roots, which might contribute to the maintenance of the root growth, resulting in the increase of the root/shoot ratio. Relatively high CK levels might be involved, together with ABA, in the suppression of lateral root formation.

CKs seem to have an important function at the initial phase of heat stress, when enhanced evapotranspiration was reported to be necessary for cooling of leaf surface (Zhang et al., 2008). CK transient increase, positively affecting stomata aperture, might contribute to transient stomata opening (Vankova, unpublished results).

Plants usually respond to mild and/or short stresses by enhanced metabolic activity, which seems to be associated with increased CK levels. Tran et al. (2007) demonstrated up-regulation of the expression of genes for all CK receptors within 10 min of dehydration. Expression of *AHK2* was also stimulated by NaCl and ABA, *AHK3*, and also by high salinity and cold stress. We found stimulation of genes for all CK receptors within 15 min of heat stress (Vankova, unpublished results). These data are in accordance with reports indicating that exogenous CKs increase tolerance to mild stress and speed up recovery (Itai et al., 1978), as well as positively affect recovery of stomatal conductance and net photosynthesis after rehydration (Rulcova and Pospisilova, 2001). Moreover, transcription of many stress-induced genes could be stimulated by CKs (Hare and Van Staden, 1997). Within 2 h, exogenous CKs were found to up-regulate expression of transcription factors, signaling proteins, developmental and hormonal regulators modulate primary and secondary metabolism; and stimulate energy generation (Brenner et al., 2005).

Prolonged and more severe stress usually coincides with decreased CK levels and growth suppression. While low levels of salt were reported to have positive effect on growth, high salt stress (100 mM NaCl, 3 weeks) led to growth suppression and progressive decrease of active CKs (Ghanem et al., 2008). Photosystem II efficiency started decreasing at the second week of salinization in the middle leaf, and at the end of the third week in the younger one (which indicated protection of younger leaves) (Ghanem et al., 2008).

When ozone-sensitive and ozone-tolerant accessions of *Medicago truncatula* were compared (Puckette et al., 2009), tolerant line up-regulated upon ozone exposure ABA- and auxin-responsive genes, as well as those associated with adaptive responses to stress. Down-regulation was observed in the case of photosynthesis-related genes. Sensitive cultivar up-regulated genes associated with oxidative stress, cell growth, translation, as well as CK-response genes. Most genes in sensitive accession were induced at later time periods. The authors concluded that inability to perform an early transcriptional reprogramming might be the cause for inefficient defense response, which may lead to severe oxidative stress. Thus, up-regulation of CK signaling did not appear as an effective strategy in case of severe stress.

As already mentioned in the case of auxins, regulation of endogenous CK levels in the defense to pathogens strongly depends on the type of infection. Part of the invading strategy of biotroph pathogens is biosynthesis of CKs (Lopez et al., 2008) or modulation of CK metabolism and/or signaling in plants. Down-regulation of the cytokinin oxidase/dehydrogenase activity of the host as well as

stimulation of the expression of CK receptors were reported in *Plasmodiophora brassicae* (Siemens et al., 2006). Elevated CK levels allow the pathogens to attract nutrients into the site of infection as well as delay tissue senescence (i.e., keep it metabolically active). Thus, stimulation of CK deactivation and/or down-regulation of CK signaling seem to be an integral part of plant defense.

There are also antagonists of pathogenic fungi, bacteria-producing CKs, which have positive effect on plant growth. For example, inoculation of lettuce plants with *Bacillus subtilis* resulted in elevation of endogenous CKs in plants, which coincided with increase plant growth (Arkhipova et al., 2005).

No necrotroph was found to produce CKs (Robert-Seilanianitz et al., 2007); therefore, in case of necrotrophs, plant response may involve enhanced CK production. One of the reasons might be stimulation of photosynthesis and enhanced energy formation. Elevation of physiologically active CK (isopentenyladenosine) was found upon infection of grapevine with Grapevine virus A and B (Vankova, unpublished data). Constitutive CK overproduction was found to delay/diminish progression of virus PVY<sup>NTN</sup> in tobacco (Muller, personal communication).

In order to keep equilibrium between energy formation and consumption, suppression of growth proved to be an effective strategy. Tolerance to severe drought and salt stresses was enhanced in single *ahk2* and *ahk3* mutants, and especially in the double mutant (Tran et al., 2007). However, positive effects of exogenous CKs on amelioration of the stress impact indicate that maintenance (at least partial) of photosynthetic activity may be beneficial. When the effect of CKs constitutively elevated before the stress initiation was followed, delay in the stimulation of defense mechanisms, e.g., increase in ABA and xanthophyll cycle pigments was observed (Havlova et al., 2008; Haisel et al., 2008). Strong overproduction of CKs by over-expression of *pssu:ipt* even enhanced plant sensitivity to drought stress (Synkova et al., 1999). This phenomenon, however, might have been caused also by the impaired root system (CK overproduction results in inhibition of formation of roots, the primary site of their biosynthesis).

Unlike constitutive CK overproduction, targeted elevation of CKs was reported to have positive effect on abiotic stress tolerance. Several authors used *SAG12:ipt* construct. *SAG12* promoter is activated at the onset of senescence in the senescing tissues. *SAG12*-driven increase of CK content then suppresses further senescence. Elevation of CKs down-regulates promoter activity, which prevents CKs from reaching superoptimal levels (high CK levels were reported to stimulate cell death, Mlejnek and Prochazka, 2002).

*SAG:ipt* transformed grass *Festuca arundinacea* Schreb exhibited improved cold tolerance (Hu et al., 2005). *SAG:ipt* Arabidopsis plants showed enhanced survival after flooding (Huynh et al., 2005). Creeping bentgrass (*Agrotis stolonifera* L.) over-expressing *SAG:ipt* showed enhanced tolerance to heat stress, exhibiting increase in number of tillers, chlorophyll retention, and root elongation. Recently, significant increase in drought tolerance was reported in tobacco over-expressing *ipt* under *SARK* (senescence-associated receptor protein kinase) promoter (Rivero et al., 2007). This promoter is activated at the very onset of senescence, prior to any visible symptoms. *SARK:ipt* plants exhibited higher WUE and better recovery after drought. They preserved the structure of chloroplasts better than WT and the rate of their photosynthesis was, under drought stress, less inhibited than in WT (Rivero et al., 2009).

Different strategies thus can be applied to diminish the negative impact of stresses: either suppression of growth and stimulation of the synthesis of protective substances or (relative) increase in photosynthesis rate to ensure supply of energy, even under unfavorable conditions. The latter strategy seems to be more promising where the crop yield is concerned. However, it should be kept in mind that in case of very strong and prolonged stresses, it might be detrimental.

Expression of *SAG:ipt* may exhibit a high potential practical impact, e.g., in delay of the postharvest senescence of cassava tuberous roots, prolonging substantially their shelf life (Kaminek, personal communication). It is necessary, however, to keep in mind the physiological consequences of delayed senescence achieved by targeted CK overproduction. Postponed senescence, found highly desirable in case of turfgrass, need not be so positive in case of wheat. Delay of leaf senescence,

achieved by *SAG:ipt* over-expression, substantially prolonged the vegetative period, increasing the sink strength of leaves, which interfered with grain filling (Sykorova et al., 2008).

### 8.3 CONCLUSIONS

Stress physiology represents a dynamically developing area with a wide potential for practical applications. The climate change, coinciding with both increase of the mean temperatures and more frequent extreme events (e.g., storms or floods), as well as the demand to feed increasing world population, indicates the necessity to grow plants in less favorable conditions, enhance stress tolerance of crops, reducing yield losses caused by different stresses and their combinations.

Until now, the most frequent strategy to improve the stress tolerance has been over-expression of transcription factors involved in signaling pathways of stress hormones. Due to the considerable cross talk among the pathways, this strategy may result in enhanced tolerance toward more stresses. However, the consequence of the constitutive activation defense metabolism is usually reduced growth under non-stress conditions. Nevertheless, as the occurrence of stresses is rather frequent and their negative impact on yield rather high, this strategy proved to be useful.

Increasing amount of evidence indicates that ROS may function as a common signal in defense pathways (Apel and Hirt, 2004; Torres and Dangl, 2005). Transient, tightly regulated increase in ROS seems to induce signaling pathways, which involve mitogen-activated kinases, transcription factors, antioxidant enzymes, dehydrins, low-temperature-induced heat shock proteins, and pathogenesis-related proteins (Gechev et al., 2006). These common signals allow increasing tolerance to different stresses by stimulation of the basal level of individual components of the stress-response pathway. Improvement of antioxidant protection of plants, e.g., by enhanced level of BRs, may thus represent a promising strategy for stress-tolerance improvement.

An alternative strategy may be the protection of photosynthesis by elevation of CKs, associated with the suppression of the (stress-induced) senescing process. Thus, targeted elevation of CKs might be useful in elevation of the tolerance to different abiotic and biotic stresses.

The achieved results indicate that modulation of hormone metabolism and/or signaling may represent a promising strategy, especially in combination with suitable tissue- and time-specific promoters.

## 9.1 INTRODUCTION

Plants face frequent periods of environmental stress that impairs their growth and reproductive capacity. Restriction of plant growth cannot be attributed to one single process, because plant growth is the result of many integrated and regulated physiological and biochemical processes. To survive and maintain minimal growth potential, plants must conform to extreme environmental conditions entailing adaptive changes in metabolism and cell composition. Of the various mechanisms enabling plants to cope with water stress, the most common is the accumulation of intracellular solutes, such as sugars and free amino acids. The most frequent nitrogen-containing compounds that accumulate in plants subjected to drought and salinity are amides, amino acids, and polyamines. The accumulation of proline on dehydration due to water deficit or increasing osmotic pressure is the most recent information concerning the osmoregulatory role of proline in environmentally stressed plants.

Salinity is a permanent threat to crops, especially in countries where irrigation is an essential aid to agriculture. It is estimated that about 20% of cultivated lands and 33% of irrigated agricultural lands worldwide are afflicted by high salinity. Moreover, the salinized areas are increasing at a rate of 10% annually. Droughts are an inevitable and recurring feature of world agriculture, and, despite our improved ability to predict their onset and modify their impact, they remain the single most important factor affecting world food security and the conditions and stability of the land resource from which that food is derived. Drought involves osmotic stress, while salt stress involves both, osmotic stress, by limiting absorption of water from soil, and ionic stress, resulting from high concentrations of potentially toxic salt ions within plant cells. In glycophytes, high salinity reduces growth by inhibiting important physiological processes, such as photosynthesis and nutrient supply to the growing tissues that are directly affected by the reduction of leaf water potential. Nutrient disturbances under both drought and salinity reduce plant growth by affecting the availability, transport, and partitioning of nutrients. Drought reduces both nutrient uptake by the roots and transport from the roots to the shoots, because of restricted transpiration rates and impaired active transport and membrane permeability (Alam, 1999). Under salinity, reduced plant growth is related to specific ion toxicities such as  $\text{Na}^+$  and  $\text{Cl}^-$  and ionic imbalances acting on biophysical and/or metabolic components of plant growth (Grattan and Grieve, 1999). Although increasing the supply of nutrients to the growth medium under drought or saline conditions can alleviate the adverse effects of either stress on plant growth, it is generally accepted that such increases will not improve plant growth when the nutrient is already present in the soil in sufficient amounts and the drought or salt stress is severe. A variety of protective mechanisms have evolved in plants to allow them to acclimatize to these unfavorable environmental conditions for survival and growth. The synthesis and accumulation of low molecular weight metabolites, known as compatible solutes, is a ubiquitous mechanism for osmotic adjustment in plants. Their main role is to increase the ability of cells to retain water without affecting the normal metabolism. Amino acids, sugars, polyols, and various quaternary ammonium compounds are reported to accumulate as compatible solutes in many plant species. Betaines, quaternary ammonium compounds occurring naturally in a variety of plants, animals, and microorganisms and proline are among the most common nitrogen containing compatible compounds. Both have been reported to be involved in the stabilization of proteins and cell structures and/or in scavenging of free radicals, and might serve to store nitrogen that can be used by the plant when the stress is relieved.

## 9.2 OSMOREGULATION OR OSMOTIC ADJUSTMENT

The osmotic potential of cytoplasm is a dynamic cell property that can change when plants are subjected to saline conditions or dehydration, as reported in an early work by Eaton (1927) and subsequently by many other investigators (Morgan, 1984). Salinized plants take up salt from the soil in quantities that decrease the osmotic potential of the cells. Bernstein (1961) termed this change “osmotic adjustment” because the cell osmotic potential paralleled the lowered water potential of the salt-affected soil, thus maintaining a favorable osmotic force for water uptake and a high turgor pressure in the cells. A similar adjustment was later discovered when plants underwent dehydration (Meyer and Boyer, 1972). The term osmotic adjustment is now applied both to dehydrated and salt-affected plants, and is defined as an accumulation or *de novo* synthesis of solute per cell that causes a change in the cell osmotic potential. It excludes changes in cell water content that also can alter cell osmotic potential. Water deficits have been shown to induce a lowering of the osmotic potential in crops as a means of maintaining their turgor (Boggess et al., 1976). This decline in the osmotic potential as a response to water deficit can be achieved by solute accumulation within the plant cell or by a decreased cell volume leading to an increased concentration of osmotic solutes as water leaves from the vacuole. These phenomena are described as osmoregulation and osmotic adjustment. *Osmoregulation* has been defined as “the regulation of osmotic potential within a cell by the addition or removal of solutes from solution until the intracellular osmotic potential is

approximately equal to the potential of the medium surrounding the cell” (Turner and Jones, 1980). *Osmotic adjustment* refers to the lowering of the osmotic potential due to the net accumulation of solutes in response to water deficits or salinity (Turner and Jones, 1980). Osmotic adjustment is an important mechanism in drought tolerance, because it enables (1) a continuation of cell expansion (Hsiao et al., 1976; Wyn Jones and Gorham, 1983), (2) stomatal and photosynthetic adjustments (Ludlow, 1980), (3) better plant growth, and (4) yield production (Morgan, 1983). The compounds involved in osmotic adjustment are mainly soluble sugars, potassium, organic acids, chloride, and free amino acids (Cutler and Rains, 1978; Jones et al., 1980). The degree of the osmoregulatory processes is affected by the rate of stress, stress preconditioning, the organ type, and the genetic variation between and within species (Morgan, 1984). It is accepted that the nontoxic compatible organic solutes accumulate in the cytoplasmic compartment of cells and inorganic ions toxic to metabolic processes are restricted to the vacuolar compartment. Considerable research has been conducted to characterize the accumulation of proline, a compound known to contribute to the osmotic adjustment and tolerance of plants exposed to unfavorable environmental conditions. How much of a role it plays is still controversial and is discussed in detail in the following sections.

### 9.2.1 PLANT RESPONSE TO DROUGHT AND SALINITY

Abiotic stress leads to a series of morphological, physiological, biochemical, and molecular changes that adversely affect plant growth and productivity (Wang et al., 2001). Drought and/or salinization are manifested primarily as osmotic stress, resulting in the disruption of homeostasis and ion distribution in the cell (Serrano et al., 1999; Zhu, 2001). Plants respond to osmotic stress caused by drought or salinity at the morphological, anatomical, cellular, and molecular levels (Greenway and Munns, 1980; Bohnert et al., 1995; Yeo, 1998; Hasegawa et al., 2000). These include, for example, morphological and developmental changes such as life cycle, inhibition of shoot growth and enhancement of root growth, adjustment in ion transport through uptake, extrusion and sequestration of ions, and metabolic changes such as carbon metabolism, the synthesis of compatible solutes. The deleterious effects of salinity on plant growth are associated with low osmotic potential of soil solution, nutritional imbalance, specific ion effect, or a combination of these factors (Ashraf, 1994). Some of these responses are triggered by the primary osmotic stress signals, whereas others may result from secondary stresses/signals caused by the primary signals. These secondary signals can be phytohormones, mainly abscisic acid (ABA), reactive oxygen species (ROS), and intracellular second messengers such as phospholipids. Inadequate response at one or several steps in the signaling and gene activation may ultimately result in irreversible changes of cellular homeostasis and in the destruction of functional and structural proteins and membranes, leading to cell death mechanisms (Wang et al., 2001). In general, plant responses are of three kinds: maintenance of homeostasis, detoxification of harmful elements, and recovery of growth. Plant modification for enhanced tolerance is mostly based on the manipulation of genes that protect and maintain the function and structure of cellular components. ABA signaling plays a vital role in plant stress responses as evidenced by the fact that many of the drought-inducible genes studied to date are also induced by ABA. ABA levels rise within one hour of an imposition of water stress (Bensen et al., 1988) and salt stress (He and Cramer, 1996).

Compatible solutes, or osmolytes, accumulate in organisms in response to osmotic stress. The primary function of the compatible solutes is to maintain cell turgor and thus the driving gradient for water uptake. Recent studies indicate that compatible solutes can also act as free-radical scavengers or chemical chaperones by directly stabilizing membranes and/or proteins (Hare et al., 1998; McNeil et al., 1999; Diamant et al., 2001). The compatible solutes generally found in higher plants are low molecular weight sugars (Garcia et al., 1997; Goddijn and van Dun, 1999), organic acids, polyols (Smith and Phillips, 1980; Abebe et al., 2003), and nitrogen containing compounds such as amino acids, amides such as glutamine and asparagine, imino acids, ectoine, proteins and quaternary ammonium compounds (Rabe, 1990; Rhodes and Hanson, 1993; Pareek et al., 1997; Mansour, 2000;

Carillo et al., 2008). Overexpression of compatible solutes in transgenic plants can result in improved stress tolerance (Sakamoto and Murata, 2002; Mattana et al., 2005; Pasquali et al., 2008).

### 9.2.2 ROLE OF PROLINE IN WATER- AND SALT-STRESSED PLANTS

Although its role in plant osmotolerance remains controversial, proline is thought to contribute to osmotic adjustment, detoxification of ROS, and protection of membrane integrity. Proline accumulation is believed to play adaptive roles in plant stress tolerance and has been proposed to act as a compatible osmolyte and to be a way to store carbon and nitrogen. Salinity and drought are known to induce oxidative stress. Early in vitro studies showed that proline can be a ROS scavenger. Proline has also been proposed to function as molecular chaperone stabilizing the structure of proteins, and proline accumulation can provide a way to buffer cytosolic pH and to balance cell redox status. Finally proline accumulation may be part of the stress signal influencing adaptive responses.

Proline may act as a component of signal transduction pathways that regulate stress responsive genes in addition to its previously described osmoprotective roles, thereby improving the tolerance to salt stress. Proline has been thought to have an adaptive role in mediating osmotic adjustment and protecting subcellular structure in stressed plants. Synthesis, degradation, and transport of proline cooperatively control its endogenous level in higher plants in response to environmental conditions. The physiological functions of proline are shown in Figure 9.1.

In *Pancreaticum maritimum* L., salt stress resulted in a decrease in the amount of ubiquitin conjugates, (a small protein targeting damaged proteins for degradation via the proteasome), particularly in the roots, and this effect was reversed by exogenous proline (Khedr, 2003). Severe salt stress resulted in an inhibition of the antioxidative enzymes, catalase and peroxidase, as revealed by spectrophotometric assays and activity gels, but the activity of these enzymes was also maintained significantly higher in the presence of proline. Salt stress also upregulated several dehydrin proteins, analyzed by western blotting, even in nonstressed plants. Thus, proline could act as a component of signal transduction pathways that regulate stress responsive genes in addition to its previously described osmoprotective roles, thereby improving the tolerance to salt stress. In ice plant (*Mesembryanthemum crystallinum*), barley (*Hordeum vulgare* L.), and wheat (*Triticum aestivum* L.) proline has a bifunctional role in the acclimation to high salt stress; an osmoregulant role in the light, and a substrate for dark respiration to supply energy for compartmentation of ions into vacuole in the dark (Sanada et al., 1995). In *Cordyline fruticosa*, proline plays an osmoregulatory role, increasing in roots not only when NaCl concentration in the nutrient solution is too high but also

**FIGURE 9.1** The physiological functions of proline. Proline has been shown to exhibit multiple functions other than osmoprotection in vitro. However, the mechanism by which proline confers stress tolerance in vivo remains poorly understood. Although proline is accumulated in many bacterial and plant cells in response to osmotic stress, proline levels are not increased under various stresses in *S. cerevisiae*. (From Takagi, H., *Appl. Microbiol. Biotechnol.*, 81, 211, 2008.)

when it is too low (Plaza et al., 2009). In some cases, proline as a free radical scavenger may be more important in overcoming stress than in acting as a simple osmolyte (Hong et al., 2000). Mattioli et al. (2008) suggested that proline plays a key role in flower transition, bolting, and coinflorescence formation. The considerable increase in free proline content in the leaves of acclimated barley plants was of a minor importance for its tolerance to dehydration (Bandurska, 2001), suggesting that proline accumulation alone is not a sufficient factor in the development of leaf dehydration tolerance to severe water deficit. The role of proline in *Halimium halimifolium* and *Pistacia lentiscus*, two contrasted species of Mediterranean shrubs, seems to be more related to a protective action in cases of severe stress conditions rather than as an osmotic agent with an osmotic potential depressing activity (Ain-Lhout et al., 2001). In *Sesbania sesban*, proline fully alleviated the salt stress induced enhancement of ribulose-1, 5-bisphosphate oxygenase activity, suggesting that proline accumulation in plants under stress must be assisting plants in maintaining the photosynthetic efficiency and the overall productivity (Sivakumar et al., 2000). Proline synthesis and its subsequent accumulation in aquatic plants is a consequence of intracellular ionic adjustments that take place under salt stress to keep the metabolic activities going on (Rout and Shaw, 1998).

### 9.3 PROLINE METABOLISM

Proline metabolism is a typical mechanism of the biochemical adaptation in living organisms subjected to stress conditions. Mitochondria have an important role regarding proline homeostasis during water stress. In many plants, proline accumulates in response to water stress and rapidly disappears upon recovery, due to variations in its cytosolic synthesis and mitochondrial degradation rates (Kiyosue et al., 1996). Moreover, since proline synthesis from glutamate requires two molecules of cytosolic NADPH, and its reverse oxidative degradation in mitochondria generates FADH<sub>2</sub> and NADH, it has been suggested that glutamate–proline cycling between cytosol and mitochondria could have a major role in redox homeostasis and metabolism (Hare and Cress, 1997). Proline metabolism is regulated by feedback inhibition mechanism (Hare and Cress, 1997; Hong et al., 2000). The synthesis of proline may have an additional effect. Intermediates in proline biosynthesis and catabolism such as glutamine and  $\Delta^1$ -pyrroline-5-carboxylic acid (P5C) can increase the expression of several osmotically regulated genes in rice (*Oryza sativa* L.), including *salT* and *dhn4* (Iyer and Caplan, 1998). Proline as a free radical scavenger may be more important in overcoming stress than in acting as a simple osmolyte.

#### 9.3.1 PROLINE SYNTHESIS

The pathway of proline biosynthesis was first elucidated in *Escherichia coli* in 1952, but only confirmed in 1987 (Leisinger, 1987). Proline biosynthesis is initiated with the ATP-dependent phosphorylation of glutamic acid by the  $\gamma$ -glutamyl kinase ( $\gamma$ -GK), encoded by the *proB* gene. The product of  $\gamma$ -GK is reduced to glutamic-semialdehyde (GSA) by the  $\gamma$ -glutamyl phosphate reductase ( $\gamma$ -GPR) encoded by the *proA* gene (Turchetto-Zolet et al., 2009). GSA cyclizes spontaneously to form P5C, which is finally reduced to proline by P5C reductase (P5CR, encoded by the *proC* gene). The proline biosynthetic route in plants resembles the bacterial pathway and uses either glutamic acid (Stewart, 1981) or ornithine (Mestichelli et al., 1979) as substrates. In plants, proline synthesis is regulated by end-product inhibition (Noguchi et al., 1968; Boggess et al., 1976). Under normal physiological conditions, both pathways contribute to proline synthesis in the cytosol. Under stressful conditions, proline is synthesized preferentially from glutamic acid (Delauney and Verma, 1993) via two intermediates: GSA and P5C. In common reed plants, free proline content and pyrroline-5-carboxylate synthetase (P5CS) activity increased with salt stress treatment, while ornithine aminotransferase (OAT) activity appeared to be unaffected, suggesting that the glutamate pathway, rather than the ornithine pathway, plays a vital role in proline accumulation during osmotic regulation (Zhen and Ma, 2009). Proline synthesis in plants can be manipulated by eliminating feedback regulation of the key regulatory enzyme of the pathway, P5CS.

### 9.3.2 PROLINE CATABOLISM

Proline accumulation and catabolism play significant roles in adaptation to a variety of plant stresses including osmotic stress, drought, temperature, freezing, UV irradiation, heavy metals, and pathogen infection. The ability of plants to degrade proline through an oxidation process has been shown clearly (Stewart, 1981). Accumulated proline is rapidly oxidized back to glutamate when osmotic stress is relieved. The first step of this process is catalyzed by a mitochondrial proline dehydrogenase (oxidase) (Sweetlove et al., 2007). Studies in *Arabidopsis* have shown rapid transcript response of proline oxidase to changing osmotic pressure, suggesting that it is a regulatory link in proline homeostasis in plants. The subsequent step in this pathway is catalyzed by delta1-pyrroline-5-carboxylate dehydrogenase. The expression of this mitochondrial enzyme is regulated by osmotic stress in *Arabidopsis* (Deuschle et al., 2001) and has recently been shown that it can act in tandem with the stress-related gene transcript to generate two types of small interfering RNAs (siRNAs) which participate in a complex manner to regulate salt tolerance (Borsani et al., 2005). The occurrence of two separate translocators for proline in the mitochondria, namely a carrier solely for proline and a proline/glutamate antiporter en route to its catabolism was shown in durum wheat (Di Martino et al., 2006). Proline (accumulated/synthesized in the cytosol) enters mitochondria via its own uniporter; inside the mitochondria Pro catabolism takes place at a rate exceeding that of the transport, as shown by the lack of accumulation of proline in the matrix; Glu is then exported outside mitochondria in exchange for further Pro via the Pro/Glu antiporter. The catabolism of proline in the mitochondria has been suggested to play multiple roles in plant physiology. It can raise the energetic status of the cell following the relief of stress conditions in addition to acting as an available reservoir of carbon and nitrogen (Hare and Cress, 1997). Recently, association between proline and programmed cell death has been reported with proline-treated plant cells undergoing a necrotic response with features consistent with the production of ROS and programmed cell death (Deuschle et al., 2004). It has been suggested to be important in the protection of catalase, peroxidase, and Complex II activities (Hamilton and Heckathorn, 2001; Ozturk and Demir, 2002). In all instances, it would appear likely that the mitochondrially localized enzymes responsible for the degradation of proline play a prominent regulatory role in these processes. The activity of the proline degrading enzyme, proline dehydrogenase (PDH), decreased under salt stress in common reed plants, indicating that proline catabolism may be responsible for proline accumulation in response to salt stress (Zhen and Ma, 2009).

### 9.3.3 ENDPRODUCT INHIBITION

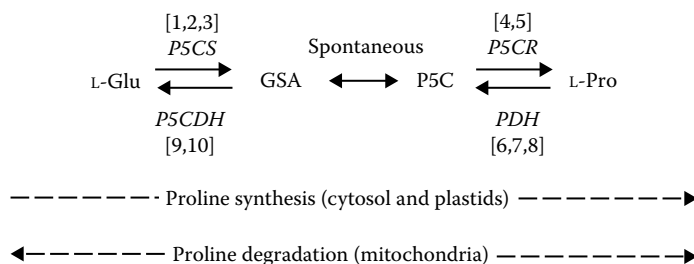

Proline manifests a conspicuous ability to control its own biosynthesis. Exogenous application to plant tissues of an amount of proline sufficient to increase the endogenous pools enhanced the rate of proline oxidation as a result of a feedback inhibition process (Stewart, 1972; Boggess et al., 1976). It is known that proline oxidase, one of the enzymes involved in proline degradation, can be induced by high concentrations of proline (Boggess et al., 1976; Adams and Frank, 1980). Feedback inhibition of proline synthesis does not occur under water-stress conditions. In sorghum and chickpea, feedback inhibition of P5CS by proline during moisture stress was observed (Dalvi et al., 2007). In bacteria, proline biosynthesis has been shown to be regulated by the end-product inhibition of  $\gamma$ -GK activity (Smith et al., 1984). A similar situation was also observed in plants. The  $\gamma$ -GK activity of Vigna P5CS was inhibited by proline, but its GSA dehydrogenase activity was not affected, suggesting that the  $\gamma$ -GK is the rate-limiting step in proline biosynthesis in plants (Zhang et al., 1995). The P5CS is the rate-limiting enzyme in proline (Pro) biosynthesis in plants which is encoded by two highly homologous genes in *Arabidopsis* and many other plants, and is subject to feedback inhibition by proline (Yoshiba et al., 1997; Fujita et al., 1998; Ginzberg et al., 1998). It is controlled at the level of P5CS transcription and through feedback inhibition of P5CS by proline (Zhang et al., 1995; Hong et al., 2000).

### 9.3.4 GENETIC MANIPULATIONS, OVEREXPRESSION OF GENES, AND TRANSCRIPTIONAL REGULATION OF GENES INVOLVED IN PROLINE SYNTHESIS

In plants, many key enzymes of metabolic pathways are generally encoded by redundant genes, which may be generated by gene duplication events during the evolutionary history of the organisms. Gene duplication produces two functionally identical copies that act in a totally redundant way immediately following the duplication event, and are often followed by sequence alterations causing changes in transcriptional regulation and contributing to evolution of functional divergence. The genetic manipulations of proline metabolic pathways in plants are summarized in Figure 9.2.

Effects of genetic manipulation of proline synthesis can be plant species specific. Overexpressing soybean *P5CR* gene in transgenic tobacco did not increase osmotolerance (Szoke et al., 1992). The overexpression of the *P5CS* encoding gene in transgenic tobacco plants resulted in increased proline production and conferred tolerance of these plants to osmotic stress, confirming that *P5CS* is of key importance for the biosynthesis of proline in plants (Kishor et al., 1995). Field trials in South Africa with *P5CR* transgenic soybean lines supported improved drought performance and higher heat tolerance compared to wild type cultivars (de Ronde et al., 2004). However, mutants displaying higher proline accumulation can also be salt hypersensitive (Lui and Zhu, 1997).

It has been shown that transcriptional control of the *P5CS* gene is important for the regulation of accumulation of proline during osmotic stress in plants. Studies of transcriptional regulation of genes involved in proline synthesis confirmed developmental regulation. In young *Arabidopsis* plants, beta-glucuronidase (GUS) analysis of *AtP5R* (*Arabidopsis P5CR* gene) promoter revealed high expression in apical meristem and young leaf, in root meristem, secondary root primordia and root vascular cylinder. In young leaf high *P5R* expression could be detected all over the leaf blade,

**FIGURE 9.2** Genetic manipulations of proline metabolic pathways in plants. The main precursor of proline synthesis is L-glutamic acid (L-Glu). L-Glu is first reduced to glutamate semialdehyde, which spontaneously cyclizes to pyrroline-5-carboxylate (P5C), by P5C synthase (P5CS). The second reduction, of P5C to proline, is catalyzed by P5C reductase (P5CR). This pathway is found in the cytosol and in plastids. Proline is catabolized to Glu in mitochondria by proline dehydrogenase (PDH) and P5C dehydrogenase (P5CDH). Examples of genetic manipulations of proline metabolic pathway and impact on osmotolerance: [1] Overexpression of mothbean *P5CS* in tobacco plants. Those transgenics were better salt tolerant (Kishor et al., 1995); [2] Overexpression of *P5CS* in antisense orientation in *Arabidopsis* (Nanjo et al., 1999a) and [3] *p5cs1* insertional mutation (Székely et al., 2008) resulted in reduced osmotolerance; [4] Overexpression of soybean *P5CR* gene in tobacco (Szoke et al., 1992) did not modify osmotolerance; [5] Overexpression of *Arabidopsis P5CR* (*AtP5R*) gene in soybean improved drought and heat stress (de Ronde et al., 2000, 2004); [6] Overexpression of *PDH* did not change osmotolerance in *Arabidopsis*, except in the presence of exogenously supplied Pro. In these conditions *PDH*-sense lines were better osmotolerant than WT. [7] Higher salt tolerance was observed in *Arabidopsis* plants overexpressing *PDH* in antisense orientation by Nanjo et al. (1999b), but not by Mani et al. (2002). Study of modifications of Pro catabolism in *Arabidopsis* in relation to P5/GSA and/or proline toxicity: [6] Overexpression of *PDH* decreased sensitivity to externally supplied proline; [7] decrease of *PDH* activity by antisense strategy (Mani et al., 2002); or [8] knock-out mutation (Nanjo et al., 2003) increased sensitivity to Pro; [9] *P5CDH* overexpression decreased sensitivity to externally supplied proline (Deuschle et al., 2004); [10] *p5cdh* knock-out mutants were hypersensitive to proline (Deuschle et al., 2004) (From Verbruggen, N. and Hermans, C., *Amino Acids*, 35, 753, 2008.)

while in old leaves, expression was restricted to the veins, hydathodes, guard cells and base of trichomes (Hua et al., 1997). In flowering plants, high *AtP5R* expression could be detected in rapidly dividing cells, such as root meristem, and cells or tissues undergoing changes in water potential, such as hydathode, guard cell, ovule, developing seed, and pollen grain (Hua et al., 1997). *AtHAL3a*, an *HAL3* homolog gene in *Arabidopsis thaliana* overexpressing transgenic plants exhibit improved salt and sorbitol tolerance (Ikuko et al., 2004). Overexpression of *NtHAL3a* improved salt, osmotic, and lithium tolerance in cultured tobacco cells. Proline degradation can also be manipulated and depends on prior proline transport to mitochondria. Overexpression of *PDH* in *A. thaliana* did not result in morphological abnormalities, probably because proline homeostasis relies on regulated transport between cell compartments (Nanjo et al., 1999; Mani et al., 2002).

### 9.3.5 IMPACT OF ENVIRONMENTAL STRESSES ON PROLINE

Proline accumulation is a common physiological response in many plants in response to a wide range of biotic and abiotic stresses. Extensive research in this area has revealed proline accumulation as a universal response of plants under stress. Proline accumulation in dehydrated plants is generally due to the concerted activation of proline biosynthesis in the cytosol and inhibition of its catabolism in the mitochondria (Kiyosue et al., 1996). Proline accumulation due to water or salt stress results from a stimulated synthesis in the tissue, an inhibited oxidation, or an impaired incorporation of proline into proteins. Clearly, under such conditions, the mechanisms of feedback inhibition cannot function. Indeed, this was proven by Boggess et al. (1976) who showed that proline does not inhibit its own synthesis in wilted barley and tobacco leaves. The increased synthesis of proline due to wilting seems to be related to the first step of this synthesis. On the other hand, water stress and salinization inhibit proline oxidation in the mitochondria and alter the permeability of the mitochondrial membrane (Miller et al., 1971; Nir et al., 1971; Sells and Koeppel, 1980). Further, the incorporation of proline into protein is inhibited by water stress, thereby also leading to proline accumulation under stress conditions (Stewart et al., 1977). The step affected in protein synthesis is probably the translation step (Hsiao, 1973); however, this process is not obligatory, because proline accumulation was observed when protein synthesis inhibitors, such as cycloheximide, were applied (Boggess and Stewart, 1980). The state of the hormonal balance in plants is suggested to play a considerable role in mediation of proline accumulation under water or salt stress (Boggess and Stewart, 1980). The key role in the osmotic adaptation of plants has been ascribed to ABA. The reduction in turgor is accepted as the primary trigger of proline accumulation in plants subjected to conditions of drought and salinity. The loss of turgor activates a complex sequence of adaptive events correlated to the level of stress, plant tolerances, and plant growth.

## 9.4 PROLINE ACCUMULATION AS AN OSMOREGULATORY RESPONSE

Proline interacts with enzymes to preserve protein structure and activity within the cell. In vitro studies have shown that high concentrations of proline reduce enzyme denaturation attributable to heat, freeze-thaw cycles, and high NaCl (Pollard and Wyn Jones, 1979; Rajendrakumar et al., 1994). Moreover, proline protects proteins and membranes from damage by inactivating hydroxyl radicals or other highly reactive chemical species that accumulate when stress inhibits electron-transfer processes (Smirnoff and Cumbes, 1989).

The accumulation of proline seems to be associated with adaptation to temperature stress. Free proline concentrations increased under both high (Ashraf et al., 1994) or low temperature (Tarnizi and Marziah, 1995; Wang and Cui, 1996), and proline could serve as a stress indicator in plants exposed to these unfavorable growth conditions. Heavy metals or herbicides are other environmental factors that induce proline accumulation in plants. *Vicia faba* plants grown in hydrocarbon-polluted soils accumulated high levels of proline (Malallah et al., 1996). High-Pb concentrations reduced sunflower plants' biomass but increased the concentration of free proline (Kastori et al., 1996).

The leaf proline content also increased in pea plants (Kamenova-Yukhimenko et al., 1995) or *Vigna radiata* (Arora and Saradhi, 1995) grown in nutrient solutions containing high-Cd concentrations. Chlormequat given to soybean plants increased the leaf proline content (El-Kheir et al., 1994). The foliar application of paraquat and diquat to *Parthenium hysterophorus* resulted in a reduction of the proline level 48 h after application followed by an increase 72 h after spraying (Kore and Patil, 1995). The foliar application of fomesan, imazaquin, metobromuron, and mettolachlor to soybean plants resulted in reduced levels of proline and some other amino acids, probably because of a disturbed protein synthesis (Stoirnenova and Stoyanova, 1995). Chlorsulfuron, norflurazon, and triallate increased the proline content in pea and *V. faba* (Fayez and Kristen, 1996). Increased levels of proline were also found in barley plants infested with aphids because of low water potentials (Fayez and Kristen, 1996). It is suggested that the changes in proline could be considered as a protective/adaptive mechanism against expected injuries resulting from pollution or herbicides.

Proline accumulation in dehydrated plant tissues was first noted in 1954 by Kemble and Mac-Pherson. Further experiments showed that the de novo synthesis of proline was involved, as the amounts were greater than those released by proteolysis. Proline accumulation was observed in many species as a result of exposure to water or salt stresses. Several reports correlate this phenomenon with stress resistance indicating that a better performance and survival can be expected in species that accumulate proline. Much evidence is available to corroborate the proline action as a compatible solute regulating and reducing water losses from dehydrated cells. The increase in the proline content during water stress is inversely proportional to the initial proline concentration in plant organs (Venekamp and Koot, 1988). It was found that the generative parts of bean plants contained considerably lower concentrations of proline than the vegetative parts after withholding water. The accumulation of proline during tissue dehydration is time dependent (Rajagopal et al., 1977). The accumulated proline is lost rapidly as a result of recovery from water stress but not as an immediate response to salt removal from the media.

All the above-mentioned points are addressed in detail in the following sections.

#### 9.4.1 OSMOTIC ADAPTATION OF BACTERIA AND ALGAE

Generally, microbes respond to water potentials by accumulating intracellular compounds that are compatible with the cellular metabolic function. There is a natural ranking or differing osmolyte preferences among species of bacteria (Csonka, 1989). The accumulation of compatible solutes in soil bacteria cells subjected to increased salinity depends either on direct uptake from the soil solution (or the rhizosphere) or on biosynthesis via the uptake of a direct precursor such as choline (Dupont et al., 2003). Both mechanisms occur simultaneously in a majority of bacteria, as in *Sinorhizobium meliloti*. *Azotobacter chroococcum*, *Azospirillum brasilense*, and *Klebsiella pneumoniae*, which are adversely affected by high osmotic strength, show osmotic adjustment when exposed to these conditions. *A. chroococcum* ZSM4 accumulates trehalose and glutamate, proline and glutamate in *A. brasilense* SHS6, and trehalose and proline in *K. pneumoniae* (Madkour et al., 1990). Glycine betaine was accumulated in all strains. This chapter focuses on betaine transport and glycine betaine biosynthesis in this bacterium, a typical representative of the rhizosphere and the microsymbiont of lucerne root nodules. Also covered are the salt tolerance of various Rhizobiaceae strains and their capacity to use choline and glycine betaine as osmoprotectants. Partial alleviation of salt stress was obtained by adding low concentrations of proline or betaine to the growth medium of *Thiobacillus ferrooxidans* (Kieft and Spence, 1988). Similar results were obtained for *Rhizobium* species (Gloux and Le Rudulier, 1989). In response to increased salt concentrations, algae also synthesize osmoregulatory solutes to counterbalance the low water potential of the growth media. Some nitrogen-fixing cyanobacteria (blue-green algae) display remarkable abilities to survive water stress, experienced either as salinity or as drought. Survival during water stress is achieved by regulation of ion fluxes for immediate osmotic adjustment to rapidly prevent turgor loss, and by a long-term adaptation plan, facilitated through selective expression of "tolerance" genes and novel

stress proteins. Such osmotic adaptation comprises of accumulation of compatible solutes conducive to metabolism and repair of oxidative damage caused by excess of free radicals. A variety of osmolytes are synthesized such as sugars, polyols, and betaines, respectively conferring low, medium, and high level of tolerance (Apte, 2001). Proline plays a key role in the osmoregulatory mechanism of *Chlorella autotrophica* (a marine microalga) when exposed to high salinities (Ahmad and Hellebust, 1984). In this alga, proline accumulation begins immediately after an osmotic shock without a lag phase. This alga is not dependent on protein synthesis and requires light, because photosynthesis supplies the required energy for proline biosynthesis.

#### 9.4.2 ACCUMULATION OF PROLINE IN CALLUS CULTURES AND ISOLATED CELLS

Compatible solutes were involved in the response of *Thellungiella holophila* and *A. thaliana* calli to salt stress (Zhao et al., 2009). Exogenous proline increases the cadmium accumulation in callus and regenerated shoots of *Solanum nigrum* (Xu et al., 2009). Endogenous free proline content in tomato calli increased gradually in response to elevating polyethylene glycol (PEG) concentrations (Shtereva et al., 2008). PEG-induced osmotic stress tolerance was found to be associated with the accumulation of free proline in 1-month-old calli of two indica rice genotypes (Ahmad et al., 2007). Proline increased significantly in date palm calli in response to salinity (Al Mansoori et al., 2007). During the induction stage, the increase in endogenous free proline content was more pronounced in the progeny of the cultivar which exhibited higher percentage of callus induction. Therefore, the better dedifferentiation process could be related to proline content, which adjusts the intracellular osmotic pressure between the cytoplasm and the vacuole.

Callus cultures of rice, adapted to grow under increasing levels of NaCl, accumulated considerable amounts of free proline compared with unadapted cells (Kishor, 1988). This trait was not lost when the cells were transferred through 10 passages in the absence of selection pressure and regrown on salt. On the other hand, mature embryo-derived calli from rice cultivars differing in their salt tolerance also accumulated proline when exposed to NaCl, KCl, or mannitol (Lutis et al., 1996). This accumulation did not depend on the nature of the stressing agent or the stress intensity and did not appear to be involved in osmotic adjustment; therefore, it was considered to be a symptom or injury in the stressed rice calli and not an indicator or resistance. In an embryogenic callus culture of lemon, selected for resistance to salinity, the proline concentration significantly increased as compared with control cells (Piqueras et al., 1996). The transfer of salt-tolerant cell cultures of alfalfa to NaCl-containing medium resulted in a tenfold increase in proline concentrations (Petrusa and Winicov, 1997). In *Brassica napus*, both unselected and tolerant calli responded to water stress by osmotic adjustment and proline concentration (Chandler and Thorpe, 1987). Increases in proline concentrations were approximately linear in tolerant calli, reaching a maximum of 175 dry weight and 520  $\mu$ M in selected calli. This accumulation was correlated with growth inhibition and negatively correlated with the culture age for tolerant calli. Callus cultures of *Medicago sativa* accumulated proline in response to NaCl (Shah et al., 1990). This accumulation was enhanced by calcium and was positively correlated with salt tolerance. The salt tolerance of sugar beet calli was also accompanied by a significant increase in the proline concentration under conditions of high salinity (Le Dily, 1991). The proline content in a callus culture of pearl millet grown in 1% NaCl increased more than 20-fold compared with nonsalinized controls (Das et al., 1990). Exposure of tobacco callus cultures to osmotic shock greatly enhanced the proline accumulation in proportion to the amount of absorbed sorbitol (Eberhardt and Wegmann, 1989). NaCl-resistant cell lines of tobacco increased the proline content within 5–10h after transplantation to a selective medium. In the wild strain, the proline content remained unchanged over a 24h period (Watad et al., 1983; Kiryan and Shevyakova, 1984). A correlation between the viability of cells in a saline environment and the proline content was observed. The intracellular proline concentration was positively correlated with the osmotic potential indicating that proline was a component of the osmotic adjustment of the cells (Binzel et al., 1987). Glutamate was the main source of the newly produced proline, and the relative

contribution of the catabolic pathway was small. Cell lines selected for resistance to salt stress responded to water stress by accumulating markedly more proline than the wild type (Watah et al., 1983). This response was stable through at least eight generations and was fully reversible. Similar results were obtained with cultured cells of a salt marsh grass (*Distichlis spicata* L.) (Ketchum et al., 1991). Most of the accumulated proline effective in osmoregulation was found in the cytoplasm. Therefore, it plays a major role in the osmotic adjustment of the vacuole. Cells maintained a cytoplasmic proline concentration at least one order of magnitude greater than that of the vacuole. Proline accumulation was inhibited by cycloheximide but not by actinomycin D. This indicated that mRNA translation, not mRNA transcription, is required before proline production. Reports are also available on a preferential accumulation of proline in nontolerant cells, as opposed to tolerant cells, indicating a dependence on a salinity threshold (Jain et al., 1987).

A significantly higher level of free proline content was observed in sugarcane calli grown under salt stress (Patade et al., 2008). An inverse correlation was found between the salt-tolerance and NaCl-induced proline accumulation in intact plants and cell cultures of *Salicornia europaea* L., *Chenopodium album* L. and in two cotton (*Gossypium hirsutum* L.) cultivars, although the accumulation of proline in leaves was of no importance for adaptation or survival of the plants (Shevyakova et al., 1998).

Cultured cells of sorghum exposed to water stress by the addition of PEG to the growing media increased proline content significantly (Bhaskaran et al., 1985). The magnitude of this increase was not correlated with the drought tolerance of the individual varieties ruling out the role of proline as an osmoprotectant in sorghum, as well as in other cereal crops.

#### 9.4.3 SEED GERMINATION AND PROLINE CONTENT UNDER STRESS

Most of the research on proline as an osmoregulatory compound has been carried out on the vegetative parts of plants. Little attention has been paid to the reproductive organs, especially seeds. Information on the osmotic adjustment of seeds under stress conditions is available. Drought-induced accumulation of soluble sugars, soluble proteins, free amino acids, and proline in seeds of *V. faba* L. cultivars was seen when exposed to different levels of PEG (Al Tayeb, 2006). Proline was used as an indicator of temperature stress in bean seeds (Machado et al., 2004). Proline content was used to predict the rate of deterioration in corn seed that were treated with ascorbic acid and germinated on NaCl stress condition (Anwar and Widajati, 2002). A close relationship between proline content and quality of the corn seed was found; the higher the proline content of the seeds, the lower the seed quality. Although there was a significant effect of salt stress on proline contents of all the different parts of germinating seeds of spring wheat cultivars, there was no consistent pattern of proline accumulation with time (Riaz, 2001). Salinity led to an accumulation of proline and total soluble sugar in the radicals of the sensitive genotype of *Cicer arietinum* (Soussi et al., 2001). Contents of proline, saccharides, and soluble proteins decreased in the germinating seeds during 3-d osmotic and salt stress of mung bean (*V. radiata*) (Zayed and Zeid, 1998). An approximately fourfold increase in free proline was observed prior to radical emergence in *A. thaliana* seeds (Hare et al., 2003). A dose-dependent inhibition of *Arabidopsis* seed germination by millimolar concentrations of proline capable of feedback inhibition of proline synthesis reinforced the role of proline synthesis in promoting germination. The ability of the artificial oxidants methylene blue and phenazine ethosulphate to overcome the inhibitory effects of proline suggests a functional link between elevated proline synthesis and increased oxidative pentose phosphate pathway activity and the importance of coupling of both pathways in stimulating germination. During germination of peanut seeds subjected to NaCl salinity stress, proline, and glycine–betaine concentrations in the embryonic axis increased continuously (Girija et al., 2002). Two enzymes play an important role in controlling the level of proline. Proline oxidase catalyzes the conversion of proline to glutamate, thus reducing the concentration of proline. Another enzyme, gamma-glutamyl kinase, plays an important role in the synthesis of proline. Addition of calcium chloride to NaCl-stressed peanut

seedlings lowered the proline concentration by increasing the level of proline oxidase and decreasing gamma-glutamyl kinase activities. Salinity stress, in the absence of calcium, increased proline due to reduced proline oxidase activity and increased gamma-glutamyl kinase activity both in the cotyledons and embryonic axis of peanut seedlings. Thus calcium ions increase glycine–betaine production but decrease proline levels in NaCl stressed peanut seedlings. Water absorption and germination rate of the seeds were negatively correlated with the salt stress (Zhi and Li, 2009). The contents of soluble sugar, soluble protein, and proline of the seedlings were higher in high salt stress than that in low salt stress. Germination rates of seeds of *Glycine max* and *Phaseolus vulgaris* were affected by exposure to NaCl, with critical thresholds at 9 and 12 g/L, respectively, while for *Mucuna poggei*, *Vigna unguiculata*, and *Phaseolus adenanthus*, critical thresholds were more than 21 g/L (Taffouo et al., 2008). Germination rate of *Pennisetum* Rich. was decreased significantly with increasing contents of PEG, but the radical/embryonic bud was increased (Jiao et al., 2009). Drought resistance in annual medics (*Medicago* spp.) plants is gained by their capability of proline accumulation (Ghamari-Zare et al., 2009). Seed germination of *Dianthus japonicus* was suppressed at over 200 mM NaCl and proline content was increased in adversely affected plants (Heo et al., 2007). Proline substantially accumulated in the seedlings of wheat cultivar (Doha) exposed to various levels of salt stress (Yasseen et al., 2006). There was a linear relationship between accumulation and the increase in NaCl concentration. Salt concentration of 50–100 mM increased seed germination and growth of *Elaeagnus angustifolia*, while at 300 mM, it was reduced by 50% (Yunus et al., 2006). Proline content was insignificantly changed at low salinity but remarkably increased at severe stress. There was strong negative correlation between germination capacity and increase in proline content in germinating embryos of sorghum (Thakur and Sharma, 2005). Germination percentage decreased in cultivars of sugarcane due to salinity, while proline content increased by two- to threefold over the controls (Vasanth and Rao, 2005). Increased antioxidant enzyme activity coincided with enhanced proline content in *Cassia angustifolia* (Agarwal and Pandey, 2004). Increase of membrane permeability of *Hedysarum scoparium*, *H. fruticosum* var. *laeve*, *Caragana korshinskii* and *Onobrychis viciifolia* seedlings caused by salt stress was negatively correlated with salt concentrations, while the cumulative amount of proline had no direct correlation with salt tolerance (An et al., 1995). Time at which proline accumulation peaked indicated the sensitivity of plants to salt. A decrease in germination percentage, root length, shoot length, and fresh mass of *Phaseolus mungo* was noticed with an increase in NaCl concentration (Dash and Panda, 2001). Salt stress increased proline accumulation in the cotyledons and roots of germinating groundnut seeds (Satakopan and Rajendran, 1989). Proline accumulated in the endosperm and radicals of germinating barley seeds with increasing NaCl concentrations in the growing media (Yasseen et al., 1989). This proline probably originated from the degradation of stored protein in the endosperm. Under increasing levels of salinity, germinating seeds from salt-tolerant cultivars of rice contained higher levels of free amino acids than salt-sensitive cultivars (Dubey and Rani, 1989). In contrast, irrigation of Cajeme wheat with saline water resulted in a continuous decrease in free proline in the grains (Devitt et al., 1987). This decrease was associated with increased protein concentrations suggesting either the rate of protein incorporation was accelerated under salinity or that free proline accumulation was stunted in other parts of the plant.

#### 9.4.4 OSMOTIC ADJUSTMENT IN HALOPHYTES

Halophytes are plants capable of growing and reproducing in highly saline environments. These plants usually absorb large amounts of NaCl, which is believed to be sequestered in the cell vacuoles; otherwise, enzyme activity would be impaired. Although halophytes are naturally adapted to salinity, their salt-tolerance limits are greatly influenced by their provenance and developmental stage. Halophytes are characterized by considerable asymmetry in the distribution of osmotica within their cells, particularly between the vacuole and the cytoplasm (Yeo, 1981). The tolerance of all halophytes to salinity relies on controlled uptake and compartmentalization of Na<sup>+</sup>, K<sup>+</sup>, and

Cl<sup>-</sup> and the synthesis of organic compatible solutes, even where salt glands are operative (Flowers and Colmer, 2008). Proline, known to be accumulated in the cell cytoplasm to balance the osmotic potential of the accumulated salt in the vacuole, does not play a role in the osmotic regulation of halophytes. For example, in halophytic Chenopodiaceae, such as *Suaeda monoica*, *Atriplex spongiosa* and *Arthrocnemum fruticosum*, proline accumulation was observed only at high inhibitory salinities, promoting normal growth (Doddema et al., 1986; Storey and Wyn Jones, 1997). Similar results were obtained with the halophyte *M. crystallinum* growth at 400 mM NaCl (Demming and Winter, 1986). Proline accumulation preceded the shift of crassulacean acid metabolism (CAM) in these plants, but only under light (Sanada et al., 1995). The results suggested that in *Mesembryanthemum*, proline has a bifunctional role in the acclimation to high salt stress: an osmoregulatory role in the light and as a substrate for dark respiration to supply energy for compartmentation of ions into vacuoles in the dark. Proline concentration in *Spartina* varied with N availability, although the higher accumulation could not alleviate the growth inhibition caused by the high salinity level (van Diggelen et al., 1986). *Sporobolus virginicus* showed high salt tolerance due to its ability to accumulate high sodium and the secretion of salt through leaves for osmotic adjustment to reduce the osmotic potential of the cell to avoid dehydration and death (Somsri and Arunee, 1994). All accessions of *Atriplex canescens* responded to salinity by increasing their uptake of Na, which is the primary mechanism of osmotic adjustment to salinity in this species (Glenn et al., 1996). It is suggested that differences in tendency to accumulate Na or K among *A. canescens* genotypes are related to their specialization for saline or xeric habitats, respectively. Exposure of *Saticornia europaea* to short-term osmotic shock resulted in a rapid increase in free Mg<sup>2+</sup>, followed by a five-fold increase in sugar concentration, either of which could have provided adequate osmoticum to prevent excessive water stress if mostly confined to the cytoplasm (McNulty, 1985). Subsequent adjustment can only be explained by a reapportionment of compatible osmotica within the cells. Such reapportionment would permit the osmotic adjustment in halophytes to occur primarily by the absorption of extraneous ions. *Salvadora persica*, an evergreen perennial halophyte capable of growing under extreme conditions, accumulates Na<sup>+</sup> as a primary osmoticum (Maggio et al., 2000). The concentration of Na<sup>+</sup> in leaves of salinized plants was approximately 40-fold greater than that measured in nonsalinized controls, and this was associated with significant reductions in leaf K<sup>+</sup> and Ca<sup>2+</sup> concentrations. In addition, a significant accumulation of proline, probably associated with osmotic adjustment and protection of membrane stability, occurred in roots of salinized plants. The salt tolerance of the annual halophyte *Cakile maritima* depends on the growth stage and severity of the salt stress (Megdiche et al., 2007). *C. maritima* plants, subjected to a high salt stress (particularly at 400 mM NaCl) accumulated high concentrations of proline and total soluble carbohydrates.

#### 9.4.5 NEGATIVE RESPONSE

Despite the abundance of reports on proline accumulation in plants growing under drought or salinity, a few others demonstrate a negative response as far as osmoregulation is concerned. For example, the contribution of proline to osmotic adjustment in legumes is of minor importance (Larher et al., 1987). No significant accumulation of proline in the leaves of green gram seedlings (Garg, 1987) or maize plants (Garg and Garg, 1982) was observed when grown in sodium bicarbonate or sodium carbonate salts. Increased concentrations of chloride or sulfate salts or PEG could not effectively stimulate proline accumulation in sugar cane leaves of a salt-sensitive variety (Naik and Joshi, 1983). Similarly, pigeon pea plants failed to accumulate proline at high-salinity level (Joshi, 1984). The lack of this adaptive mechanism may explain the failure to develop salt tolerance in cultivated pigeon pea or sugar cane. In a more recent work, however, salt tolerance could be found in wild relatives of pigeon pea belonging to the genera *Atylosia*, *Dunbaria*, and *Rynchosia* but without correlation between salinity tolerance and proline accumulation (Subbarao et al., 1990). In *Andropogon glomeratus*, a C<sub>4</sub> nonhalophytic salt marsh grass, proline played no role in osmotic adjustment, since very high levels of salinity are required to

increase its concentrations (Bowman, 1988). One of the adaptive mechanisms suggested as being associated with osmotic adjustment is a restriction in cell expansion (van Volkenburgh and Boyer, 1985). Extensin, a major plant cell wall glycoprotein in dicots, was found to be a hydroxyproline-rich glycoprotein (Cassab and Vamer, 1988). Therefore, some work was carried out to determine changes in cell wall protein induced by salt stress and expressed as changes in proline and hydroxyproline concentrations. No significant effect of stress on the proline and hydroxyproline contents was found in a purified cell wall fraction of sunflower (Golan-Goldhirsh et al., 1990). Therefore, changes in the physicochemical properties of the cell wall accompanying osmotic adjustment appear to lie in other posttranslational modifications of extension. Cell membrane stability of four *Arachis* cultivars exposed to PEG was tested in response to drought tolerance (Deb et al., 1996). It was found that proline was not effective in controlling the physiological status of the cell membrane and its stability. Water-stressed pea seedlings did not significantly accumulate proline (Generozova et al., 2009). Significant negative correlations were observed in barley genotypes between  $\text{Na}^+$ -induced  $\text{K}^+$  efflux (an indicator of salt tolerance) and leaf glycine–betaine and proline (Chen et al., 2007), suggesting that hyperaccumulation of known major compatible solutes in barley does not appear to play a major role in salt-tolerance, but rather, may be a symptom of salt-susceptibility. The small (twofold) increase of proline content in salinity stressed plants indicates proline does not play a significant role in olive stress response (Rejskova et al., 2007). Other reports are also cautioning its use (Lin and Kao, 2001; Hare et al., 2002; Heuer, 2003). Different plant species, proline concentrations, and treatment stages may explain the discrepancy between the effect of exogenous application of proline and its negative effects (Ashraf and Foolad, 2007).

## 9.5 EXOGENOUS PROLINE APPLICATION

Plants growing in saline environments usually accumulate large amounts of NaCl in their tissue. Because Na and Cl are inhibitory to a large number of enzymes, their presence in the cytoplasm should be minimal. Evidence of the compartmentation of electrolytes between the cytosol and the vacuole is available. The necessary osmotic balance between the two compartments is achieved through the accumulation of organic solutes in the cytoplasm. Proline is one of these compatible solutes. Besides playing an osmotic role, it should protect enzymes against denaturation or inhibition of activity. This could be determined easily by adding exogenous proline to the assay media or to crude extracts. Contradictory reports for differing plant species are known. For example, full protection of phosphoenolpyruvate (PEP) carboxylase against NaCl inhibition was obtained in two Poaceae species with a proline concentration between 200–800 mM, and proline behaved as a competitive inhibitor in Chenopodiaceae (Manetas et al., 1986). Similar results were obtained from the activities of NAD-malate dehydrogenase, glucose-6-phosphate dehydrogenase, NADP-isocitrate dehydrogenase, and glyceraldehyde phosphate dehydrogenase (Schwab and Gaff, 1990). Almost full protection of enzyme activities was obtained when proline was added at a molar ratio of 2:1 (protectant to salt) simultaneously with the addition of salt to the reaction media. No protection was found when proline was added after 1 h preincubation of enzyme extracts with high salt concentration. Extracts from air-dried leaves recovered almost fully after more than 5 h of preincubation in 1 M proline. Exogenous proline supplied to radish seedlings reduced tissue Hg levels owing to the inhibition of Hg uptake (Khanna et al., 1995).

One approach to assess the metabolic consequences of proline accumulation in response to stress is to examine its exogenous application to whole organism or tissues. Exogenously applied proline stimulated the growth of bacteria subjected to osmotic stress (Britten and McClure, 1962; le Redulier and Valentine, 1982). Proline has also been applied to higher plants to determine its ability to counteract the inhibitory effects of environmental stress, mainly water or salt stress. The exogenous application of proline has been suggested to be an effective approach in improving crop salt tolerance in groundnut (Jain et al., 2001), melon (Kaya et al., 2007), and tobacco (Hoque et al., 2007). The addition of 100 mM proline to a Hoagland solution containing 120 mM NaCl neutralized

the effect of salinity on pea plants (Bar-Nun and Poljakoff-Mayber, 1977). Incubation of *Commelina communis* epidermal tissue in proline inhibited stomatal opening (Klein and Itai, 1989). The addition of 10 mM proline to cultured barley embryos increased shoot elongation under saline conditions (Lone et al., 1987). This effect was attributed to the ability of proline to decrease the leaf salt load. Proline allowed an enhanced K/Na discrimination in transport to the shoots and a better salt exclusion from the shoots with retention in the roots. The callus lines of *C. arietinum* grown in a medium containing 100 mM NaCl and 10 mM proline increased their fresh and dry weights (Pandey and Ganapathy, 1985). Optimal concentrations of proline increased the cellular levels of K and decreased Na and Cl levels. Spraying cotton plants grown under conditions of low soil water potential with proline solutions counteracted the effects of stress, especially at moderate and high stresses (Gadallah, 1995).

Exogenous proline had no effect on the germination of tomato seeds under water or salt stress (Wu, 1987) or on the ribosome stability in the presence of 250 or 500 mM KCl (Brady et al., 1984), but it increased pollen germination when exposed to brief temperature stress (Thind and Malik, 1994). The presence of 1 or 10 mM proline in media containing 100 or 200 mM NaCl had little effect on the growth of the salt-adapted callus of rice (Kishor, 1989). Some concentrations significantly increased the growth of salt-unadapted callus. Exogenous proline has been reported to protect plants under stress. It improved the tolerance of somatic embryos of celery (*Apium graveolens* L. cv. SB 12) to partial dehydration (Saranga et al., 1992). Okuma et al. (2000) found that exogenous proline improved the growth of salt-stressed tobacco cell cultures and the improvement was attributed to the role of proline as an osmoprotectant for enzymes and membranes against salt inhibition rather than as a compatible solute. Exogenous proline partly alleviated growth of *Pancreaticum* seedlings reduced by salt stress (Khedr et al., 2003). Proline induces the expression of salt-stress-responsive proteins and may improve the adaptation of *P. maritimum* L. to salt stress. The ability of exogenous proline to maintain higher water content in severely stressed seedlings might be attributed to its contribution to osmotic adjustment both directly by increasing the internal proline content and indirectly by increasing the internal contents of other amino acids. Exogenous proline increased the protein content of the shoot and root at all levels of salt stress. Changes in growth and protein contents as a result of exogenous proline correlated with increases in the internal content of proline suggesting that proline was taken up into the roots and transported to the shoots. Ion fluxes across the plasma membrane may be regulated by low concentrations of proline in barley roots (Cuin and Shabala, 2005).

On the other hand, despite its protective role under a variety of stress conditions, external supply of proline was also found to be toxic to plant and animal cells (Hellman et al., 2000; Heuer, 2003). High concentrations of proline (50 and 100 mM) inhibited the growth of NaCl-stressed as well as NaCl-nonstressed callus cultures of mung bean (Kumar and Sharma, 1989). Proline (10 mM) inhibited the growth of salt grass suspension cultures in the presence of 260 mM NaCl (Rodriguez and Heyser, 1988). Exogenous [<sup>13</sup>C] proline inhibited the normal biosynthesis of proline that would have occurred in suspensions grown at this salinity level. It has been proposed that proline-induced damage is mediated by P5C/GSA, which, if not metabolized rapidly, might induce cell death. Exogenous proline was found to reduce the growth of roots of rice seedlings and the amount of inhibition increased with increasing the concentration of proline from 1 to 4 mM. This inhibition was attributed to the observation that proline-induced cell wall bound peroxidases which resulted in increased lignin synthesis, thereby stiffening the cell wall and reducing expansion (Lin and Kao, 2001). It has become apparent that an excess of free proline has negative or side effects on cell growth or protein functions. Intracellular proline accumulation significantly represses several genes involved in the synthesis of other amino acids or normal morphogenesis in *Arabidopsis* plants (Nanjo et al., 2003). It is also suggested that the proportion of proline to the total amino acids, rather than the concentration, influences the growth of petunia plants (Yamada et al., 2005). Furthermore, the toxicity of proline and its metabolite P5C have been considered to function as signals in stress-induced cell death (Hellman et al., 2000; Maxwell and Davis, 2000;

Morita et al., 2002; Deuschle et al., 2004; Nomura and Takagi, 2004). In *S. cerevisiae*, Maggio et al. (2002) found that intracellular proline accumulation is associated with reduced growth rate. It has also been reported that excess proline might be toxic to yeast cells only when it accumulates in the cytosol (Morita et al., 2002) or might delay yeast cell growth in the presence of ethanol (Takagi et al., 2007). Even at the enzyme level, proline overaccumulation to a concentration as low as 100 mM suppresses the activity of the major chloroplastic enzyme ribulose 1, 5-bis-phosphate carboxylase in higher plants (Sivakumar et al., 1998). These results suggest that intracellular proline must be present at an appropriate level in order to confer stress tolerance. Foliar application of proline was an effective way to improve the salt tolerance of cucumber (Huang et al., 2009). The enhanced salt tolerance could be partially attributed to the improved water status and peroxidase enzyme activity in the leaves.

The method of using exogenous proline proved that mechanism of feedback inhibition of proline synthesis exists in fully turgid plant tissues but not in stressed tissues (Boggess et al., 1976). At this point, enhanced proline oxidation also cannot be ignored. Moreover, this technique emphasized the role of proline as a compatible solute involved in the process of the osmotic adjustment of living organisms.

## 9.6 PROLINE CONTENT AS AN INDICATOR FOR BREEDING PROGRAMS

The existence in plants of quantitative variations in the physiological trait of proline accumulation in response to water or salt stresses has suggested its possible consideration as a selection criterion for breeding programs. This was indeed recommended for cereals growing in Mediterranean environments (Richards et al., 1987). Research performed with 12 paddy genotypes showed a stimulation of proline accumulation in the leaves of plants exposed to salinity (Pandey and Srivastava, 1990). The salinity index of yield showed a significant positive association with proline accumulation, prompting the suggestion of this physiological trait as one of the promising indices for breeding salt-tolerant genotypes in rice. Nitrate reductase activity and proline content were much higher in drought-resistant cultivars of paddy rice; therefore, it was suggested that these two factors may be adopted as an indicator in the identification of drought resistance in rice breeding (Liu et al., 1993). The magnitude of proline response also was suggested for screening alfalfa plants for salt tolerance (Refoufi and Larher, 1989). On the other hand, Ashraf (1989) concluded that proline accumulation cannot be used as an indicator for salt tolerance of black gram and is thus unsuitable for breeding programs. The same is true for soybeans (Moftah and Michel, 1987) and pearl millet (Chandra and Chauhan, 1983) although Petcu et al. (1995) stated that free proline content of the primary leaves appeared to be a good selection criterion in breeding for drought tolerance. Final concentrations of proline accumulated in tobacco plants are advocated as criteria to be used in selecting for drought-tolerant tobacco genotypes as early as the F<sub>1</sub>- or F<sub>2</sub>-generations (1993). Hou et al. (1990) suggested that increase of proline content in plants under soil water stress can be taken as an indicator of drought resistance. Free proline and glycine- $\beta$ -betaine accumulation in the leaves can be used as the possible indicator for drought tolerance in maize genotypes (Moussa and Abdel-Aziz, 2008). Drought resistant sugarcane plants have an enhanced ability to accumulate proline when compared with susceptible lines, making proline content a useful selection criterion (Widyasari and Sugiyarta, 1997). Proline content in storage roots of sugar beet is potentially useful as indicator of situations that lead to decreased yield and quality of the root, such as drought stress (Monreal et al., 2007). Proline accumulation can be used as an indicator of the salt stress imposed on citrus cell lines in suspension cultures (Ferreira and Lima-Costa, 2006). High relative water content (RWC) and Pro over-accumulation were recognized as beneficial drought tolerance indicators and may be used as selection criteria in wheat breeding programs (Bayoumi et al., 2008). Correlation analysis discarded proline as an indicator of drought tolerance (Farshadfar et al., 2008). It can be concluded that, in general, proline accumulation is specific to a genotype, and generalization over different varieties of a crop is not always possible.

## 9.7 CONCLUSIONS

The accumulation of proline in plants subjected to water or salt stress has been observed widely, although not universally. Several possible physiological functions have been ascribed to induced proline accumulation by water shortage. These functions include osmoregulation, a soluble N sink, a signal of senescence, and an indicator of plant resistance to stress. Proline accumulation is a common physiological response to various stresses but is also part of the developmental program in generative tissues. Proline may affect the solubility of various proteins, thus protecting them against denaturation under water-stressed conditions. An increase in the proline content may be associated with either enhanced biosynthesis, with stimulated proline oxidation, or an impaired protein synthesis. In general, proline concentrations are directly proportional to the salinity level or to the intensity of water stress. Genotype variations are very common; however, a positive correlation cannot always be found between proline content and a plant's relative tolerance or susceptibility. Restoring plants to optimal growth conditions, results in a rapid decline in the proline content. Transgenic approaches have confirmed the beneficial effect of proline overproduction during stress, although no consensus was achieved on the exact roles of proline accumulation. Classical gain or loss of function strategies could not bring clear answers, probably because proline also displays the essential role of being a protein component. Environmental stresses such as drought or salinity have multiple targets and proline is believed to play different roles. The balance between biosynthesis and degradation of proline is probably essential in the determination of the osmoprotective and developmental functions of proline. Additional studies are required to elucidate conclusively the role of proline in plant adaptation to stress.

## 10.1 INTRODUCTION: DEFINITION OF DEHYDRINS, THEIR STRUCTURE, AND FUNCTIONS

### 10.1.1 DEFINITION OF DEHYDRINS

Dehydrins are highly hydrophilic, well-soluble proteins, which belong to a large family of late embryogenesis-abundant (LEA) proteins whose name comes from Galau et al. (1986) who studied them for the first time in cotton (*Gossypium hirsutum* L.) embryos (Dure et al., 1981; Galau and Dure, 1981). They are classified as group 2 LEA (or LEA II) proteins (Bray, 1993; Ingram and Bartels, 1996) or LEA-D11 proteins according to one dehydrin member in cotton embryo (Dure et al., 1989). In Pfam database of protein domains (<http://www.sanger.ac.uk/Software/Pfam>; Bateman et al., 2004), they are simply named dehydrins and have a Pfam number PF00257. They have a relatively high glycine content (greater than 6%) and a hydrophilicity index (Kyte and Doolittle, 1982) greater than 1; thus they can be classified as hydrophilins (Garay-Arroyo et al., 2000; Battaglia et al., 2008). The first reported dehydrin proteins were RAB21, a protein induced by salt and osmotic stress in rice (*Oryza sativa* L.) (Mundy and Chua, 1988) and D-11, a protein accumulating in maturing embryo of cotton (*Gossypium hirsutum* L.) (Baker et al., 1988). At the end of the 1980s, dehydrins were defined as “dehydration-induced proteins” according to their mode of expression (Close et al., 1989). Later, as their sequence characteristics became available, dehydrins were redefined on the basis of their sequential motifs. They were newly defined as proteins possessing at least one copy of a conserved lysine-rich amino acid (aa) sequence—a K-segment—in their molecules (Close, 1996, 1997). Due to this definition based on the presence of a unique amino acid motif, dehydrins can be easily detected by a specific primary antibody raised against the K-segment (Close et al., 1993).

### 10.1.2 CLASSIFICATION OF DEHYDRINS

The K-segment is a lysine-rich aa sequence present in 1–11 copies near to the C-terminus of dehydrin molecules. Consensus amino acid sequence of K-segment in angiosperms is EKKGIME/DKIKEKLPG. Apart from the K-segment, dehydrins can possess other conserved sequential motifs: the tyrosine-rich Y-segment (consensus (V/T)D(E/Q)YGNP) near to the N-terminus and the serine-rich S-segment. S-segment is formed by a stretch of 4–10 serine residues, which are a part of a conserved sequence LHRGS<sub>4–10</sub>(E/D)<sub>3</sub>. This sequence motif can be distinguished by casein kinase II (CK<sub>2</sub>)-type kinases and plays an important role in phosphorylation of serine residues in the S-segment (Svensson et al., 2002; Battaglia et al., 2008). According to the presence of the K-, S-, and Y-segments, dehydrins can be divided into five structural subgroups: K<sub>n</sub>, SK<sub>n</sub>, K<sub>n</sub>S, Y<sub>n</sub>K<sub>n</sub>, and Y<sub>n</sub>SK<sub>n</sub> (Close, 1996, 1997; Campbell and Close, 1997). In addition, dehydrin molecules can contain less conserved sequential motifs rich in glycine and hydrophilic aa called  $\Phi$ -segments.

An alternative classification of dehydrins (group 2 LEA proteins) has recently been proposed by Wise (2003) who divided them into three subgroups—2a, 2b, and 2c—according to protein hydrophilicity, predicted secondary structure, and content of aromatic and charged aa residues. It is interesting that this classification corresponds to different protein stress induction patterns: subgroups 2b and 2c (especially 2c) include predominantly cold-inducible dehydrins while subgroup 2a includes dehydrins not inducible by cold stress.

### 10.1.3 STRUCTURE OF DEHYDRINS

#### 10.1.3.1 Primary Structure

In general, dehydrin aa sequences contain relatively large proportions of glycine (G) and hydrophilic aa, especially threonine (T). In contrast, they nearly lack cysteine (C) and tryptophan (W). These unique sequential characteristics determine high hydrophilicity of dehydrin molecules. Dehydrins are well soluble in various kinds of aqueous buffers and remain soluble in these buffers

even after boiling. This fact can be used for their enrichment in plant tissue extracts (Campbell and Close, 1997; Close, 1997). Dehydrins also exhibit enhanced affinity to detergents such as sodium dodecyl sulfate (SDS). They bind unusually high proportions of SDS when compared with most protein molecules and therefore they appear larger on SDS-PAGE gels (Their electrophoretic mobility is shifted to values typical for larger proteins on SDS-PAGE gels, i.e., their molecular weights determined on the basis of electrophoretic mobility correspond to the proteins with ca 24% higher molecular weight  $M_r$  when compared with the values calculated from dehydrin aa sequence) (Close, 1997; Ismail et al., 1999a).

### 10.1.3.2 Secondary and Tertiary Structure

In aqueous solutions, dehydrin molecules are present in the conformation of random coil, i.e., their molecules form a maximum of hydrogen bonds with neighboring water molecules (intermolecular hydrogen bonds) and a minimum of hydrogen bonds between different aa residues within protein molecules (intramolecular hydrogen bonds). Due to low proportion of intramolecular hydrogen bonds, dehydrin molecules are intrinsically unstructured. Dehydrins share many features with other types of intrinsically disordered/unstructured proteins (IDPs/IUPs) (Tompá, 2002; Tompá et al., 2005): They contain high proportions of hydrophilic aa and change their conformation according to the changes in their ambient microenvironment. Based on several experimental studies (Lisse et al., 1996; Danyluk et al., 1998; Ismail et al., 1999a; Hara et al., 2001; Kovacs et al., 2008; Mouillon et al., 2008), it was confirmed that the decrease in dehydrin hydration status (loss of water molecules in their ambient microenvironment) or addition of high amounts of compatible solutes such as glycerol, detergents such as SDS or salts such as NaCl into dehydrin aqueous solution leads to conformational changes which can be monitored by the technique of far-UV circular dichroism (CD). It was found out that under the conditions of reduced hydration, the regions of the K-segments form left-handed class A2 amphipathic  $\alpha$ -helices, i.e., they form intramolecular hydrogen bonds between different aa residues within the same protein molecules instead of intermolecular hydrogen bonds between aa residues and surrounding water molecules which predominate in random coil conformation. Random coil conformation is relatively symmetrical; thus it does not deviate the plane of linearly polarized light beams significantly, whereas  $\alpha$ -helices are highly asymmetrical, and thus deviate the plane of linearly polarized light. The amphipathicity of the resulting  $\alpha$ -helices is determined by the aa sequence of the K-segment. When  $\alpha$ -helix is formed, negatively charged aa (aa with acidic pI, e.g., D and E) lie on one side of the helix, hydrophobic aa (nonpolar aa, e.g., I and L) lie on the opposite side of the helix, and positively charged aa (aa with basic pI, e.g., K and R) lie on the polar–nonpolar interface (Svensson et al., 2002; Saavedra et al., 2006).

Some researchers (e.g., Soulages et al., 2003) suggest that some dehydrins (e.g., recombinant GmDHN1 from soybean *Glycine max*) do not form classical  $\alpha$ -helical structures after addition of detergents; instead, they rather reveal a left-handed extended poly (L-proline)-type II (PII) helical conformation. Soulages et al. (2003) emphasized that extended PII helical structures contain relatively higher portions of aa residues capable of forming intermolecular hydrogen bonds in comparison with “classical  $\alpha$ -helices” as protein secondary conformation motifs, and thus the extended PII conformations enable dehydrin interaction with membrane surfaces. It should be noted that extended PII helical conformations are typically formed by those protein molecules which have a high content of G (contain G repeats—every third aa is G) and P such as animal collagen.

### 10.1.3.3 Relationships between Dehydrin Structure and Functions

The changes in protein conformation result also in changes in protein function. This phenomenon, which is characteristic for IDPs/IUPs, is called “moonlighting” (Tompá, 2002; Tompá et al., 2005). In the case of IDPs/IUPs, the changes in protein ambient microenvironment, such as availability of water molecules, result in protein conformational and functional changes. The flexibility of protein conformation results in versatility of their functions, which mirror the changes in the protein ambient microenvironment.

In a well-hydrated state, individual macromolecules like proteins or phospholipids in biomembranes are surrounded by a thin layer of highly ordered water molecules bound to the protein or membrane surface via intermolecular hydrogen bonds (“water envelope”). Therefore, the protein or phospholipid macromolecules do not interact with each other directly. During dehydration, the “water envelope” disrupts and the macromolecules then can come into mutual interaction (Israelachvili and Wennerström, 1996). The amphipathic  $\alpha$ -helices can interact with partly dehydrated surfaces of various other proteins and also with surfaces of biomembranes. It has been proposed by Ingram and Bartels (1996) that several K-segments in one dehydrin molecule can form bundles when present in  $\alpha$ -helical conformation thus enhancing their amphipathic character in protein–protein or protein–biomembrane interactions. The binding of dehydrin molecules to the partly dehydrated surface of other protein molecule enhances formation of amphipathic  $\alpha$ -helices in a dehydrin molecule and protects the other protein molecule from further loss of water envelope, which can lead to irreversible changes in the protein conformation, i.e., protein denaturation. It has been suggested that these interactions between partly dehydrated surfaces of dehydrin molecules and partly dehydrated surfaces of other protein molecules and/or biomembranes (observed e.g., by Koag et al., 2003 in case of maize DHN1), which are enabled by the amphipathic nature of the  $\alpha$ -helices, present the basis of dehydrin protective functions such as chaperone function, “molecular shield” function and cryoprotective function. However, direct experimental evidence is still lacking.

Kovacs et al. (2008) investigated chaperone activities of two dehydrin proteins isolated from *Arabidopsis thaliana*, ERD10 and ERD14, and described their protective effects against thermal aggregation of citrate synthase, firefly luciferase, inactivation of lysozyme, and thermal inactivation of alcohol dehydrogenase. However, it turns out that the interactions between dehydrin molecules and other protein molecules are rather nonspecific protein–protein interactions when compared with the interactions of classical chaperones (e.g., small heat-shock proteins). Therefore, some authors describe these dehydrin protective functions based on nonspecific protein–protein interactions as “molecular shield” (Tunnacliffe and Wise, 2007). Under environmental conditions, when cells lose water, the relative spational (three-dimensional) proportions among individual intracellular complexes do also change. These spational changes are also harmful since they can lead to undesirable interactions and aggregation and denaturation of several protein and membranaceous complexes. It has been proposed by several scientists (Tunnacliffe and Wise, 2007; Battaglia et al., 2008) that dehydrins can accumulate to relatively large amounts in various compartments inside the cells under the conditions associated with cellular dehydration. Thus, they can simply act as “space-fillers,” i.e., they can participate in keeping the original, non-harmful distances among individual subcellular complexes. (During dehydration, cell volume diminishes and this process can lead to several undesirable protein interactions resulting in protein denaturation.) Due to their largely unfolded state, capability to bind water, and high level of accumulation, dehydrins can mimic the adverse effects of cellular dehydration and help in keeping the original cell volume, thus preventing structural collapse in the cell. This phenomenon, i.e., accumulation of various kinds of intrinsically unstructured hydrophilic proteins together with low-molecular compatible solutes, is sometimes termed “macromolecular crowding” (Ellis, 2001a,b; Mouillon et al., 2008).

Cryoprotective function, i.e., the ability to protect enzymes from the loss of their activity under freeze-thaw conditions, was first reported by Lin and Thomashow (1992) for COR15a protein, a LEA-3 protein from *A. thaliana* using a lactate dehydrogenase (LDH) assay (EC 1.1.1.27.) developed by Carpenter and Crowe (1988). Since then, a cryoprotective activity has been reported for several dehydrin proteins, e.g., COR85 from spinach (Kazuoka and Oeda, 1994), WCS120 from common wheat (Houde et al., 1995), PCA60 from peach (Wisniewski et al., 1999), CuCOR19 from *Citrus unshiu* (Hara et al., 2001), DHN5 from barley (Bravo et al., 2003), and others. As shown by Reyes et al. (2008), the presence of K-segments is essential for dehydrin cryoprotective activity.

Some dehydrins, which contain relatively large amounts of H, R, and other reactive aa residues on the surface of their folded molecules such as CuCOR15 and CuCOR19 from Satsuma mandarin (*Citrus unshiu*), exhibit also reactive oxygen species (ROS) scavenging and metal ion

binding properties. Both functions are mediated by direct interactions between the aa residue and the ROS species (superoxide anion radical  $O_2^{\cdot-}$ ; singlet oxygen  $^1O_2$ ; hydroxyl radical  $HO^{\cdot}$ ; hydrogen peroxide  $H_2O_2$ ) or the metal ion ( $Co^{2+}$ ;  $Cu^{2+}$ ;  $Fe^{2+}$ ;  $Fe^{3+}$ ;  $Ni^{2+}$ ;  $Zn^{2+}$ ). The interactions of the aa residue with ROS lead to oxidation of the residue, the interactions with metal ions lead to the formation of covalent bonds. Binding of free metal ions prevents the intracellular compounds from excessive ROS formation since free metal ions act as catalyzers of synthesis of various ROS. Dehydrins can thus function also as antioxidants (e.g., CuCOR15 and CuCOR19 in Satsuma mandarin (*Citrus unshiu*)—Hara et al., 2001, 2005), ion sequestrants (e.g., VCaB45 in celery (*Apium graveolens*) vacuoles which binds  $Ca^{2+}$ —Heyen et al., 2002), or metal ion transporters in plant phloem sap (e.g., ITP protein from castor bean (*Ricinus communis*) which binds  $Fe^{2+}$  and  $Fe^{3+}$ —Krüger et al., 2002).

#### 10.1.4 DEHYDRINS AND DEHYDRIN-LIKE PROTEINS WITHIN THE PLANT KINGDOM AND IN OTHER ORGANISMS

From the end of the 1980s until now, hundreds of dehydrin proteins have been described not only in dicotyledonous and monocotyledonous angiosperms such as cotton and rice, but also in other plant taxons including gymnosperms, ferns, lycopods, and mosses. Proteins induced by osmotic stress that contain conserved sequential motifs resembling the dehydrin K-segment have also been found in various groups of cyanobacteria (Close and Lammers, 1993), algae (Li et al., 1998), in mycelia of white truffle *Tuber borchii* from *Ascomycota* (Abba et al., 2006) and in invertebrates, which can survive cellular desiccation in “anhydrobiosis state,” e.g., some nematodes (*Aphelenchus avenae*, *Caenorhabditis elegans*) and bdelloid rotifers (Browne et al., 2002; Tunnaccliffe and Wise, 2007). To the proteins, which resemble dehydrins distantly due to the presence of sequential motifs that can form amphipathic  $\alpha$ -helices analogous to the dehydrin K-segment, belong also  $\alpha$ -synucleins, proteins found in animal neurons where they bind to vesicles with neurotransmitters (Ismail et al., 1999a; Souza et al., 2000).

Dehydrin-like proteins in cyanobacteria and algae usually accumulate inside the cells under conditions associated with osmotic stress. It was proposed that dehydrins protect the cells against excessive water loss which is important namely for those algae that inhabit intertidal zones where they have to face periodical desiccation. Li et al. (1998) detected several dehydrin-like proteins in five species of fucoid algae (*Phaeophyceae*) living in the intertidal zone; unlike dehydrins in higher plants, these proteins were denaturated by boiling.

In seedless plants, i.e., mosses, lycopods, and ferns, dehydrins have been characterized in several species. In contrast to gymnosperms and angiosperms, only one copy of dehydrin gene per genome was found in all these plant taxons (groups). Dehydrins are thus present as single-copy genes in genomes of seedless plants. In mosses, dehydrin genes were sequenced in a desiccation-tolerant moss *Tortula ruralis* (Velten and Oliver, 2001) and in *Physcomitrella patens* (Saavedra et al., 2006). Velten and Oliver found out that during desiccation of *Tortula ruralis*, the level of dehydrin mRNA increases. The researchers have hypothesized that during rehydration, the dehydrin protein Tr288 becomes translated and helps to restore intracellular complexes. Tr288 is therefore also called “rehydrin.” Near to the C-terminus, a conserved sequence which can form an amphipathic  $\alpha$ -helical structure similar to the  $\alpha$ -helices formed by angiosperm dehydrins, occurs. The dehydrin protein characterized in *P. patens*, PpDHNA, has probably a protective function in osmotic stresses since a *P. patens* knockout mutant *dhnA* reveals impaired ability to tolerate these factors (impaired growth on medium containing NaCl or mannitol). In contrast to Tr288, PpDHNA is also up-regulated by ABA. (In *Tortula ruralis*, endogenous ABA was not detected (Oliver et al., 1998).) Dehydrins were also detected in a poikilohydric fern *Polypodium virginianum* (Reynolds and Bewley, 1993) and in a resurrection lycopod *Selaginella lepidophylla* (Iturriaga et al., 2006).

In all gymnosperm and angiosperm species studied so far, more than one copy of dehydrin gene per genome was found. In other words, dehydrins are present as multicopy genes in genomes

of both gymnosperm and angiosperm plants. The different dehydrin genes identified in one plant species usually belong to different structural subgroups and reveal different modes of expression. Dehydrins in gymnosperms differ from their counterparts in angiosperms in the aa sequence of the K-segment. The consensus aa sequence of the K-segment for gymnosperms is (Q/E)K(P/A)G(M/L)LDKIK(A/Q)(K/M)(I/L)PG while for angiosperms is EKKGIMDKIKEKLPG. The first report about detection of dehydrins in gymnosperms comes from Close et al. (1993) who found a positive reaction on a polyclonal primary antibody raised against the angiosperm consensus K-segment in *Ginkgo biloba* and *Pinus taeda*. Later, Jarvis et al. (1996) detected dehydrins in Douglas fir *Pseudotsuga menziesii*. Until now, dehydrins have also been identified in white spruce *Picea glauca* (Richard et al., 2000), in Scots pine *Pinus sylvestris* (Kontunen-Soppela et al., 2000; Wachowiak et al., 2009) in Norway spruce *Picea abies* (Yakovlev et al., 2008), and in cypress *Cupressus sempervirens* (Pedron et al., 2009).

Until now, hundreds of dehydrin genes have been sequenced in different angiosperms including both dicotyledonous and monocotyledonous species. Among dicotyledons, dehydrins have already been characterized in small herbaceous plants such as the thale cress (or mouse-ear cress) *Arabidopsis thaliana* as well as in large, long-living woody species such as silver birch *Betula pendula* (Puhakainen et al., 2004a), downy birch *Betula pubescens* (Welling et al., 2004), beech *Fagus sylvatica* (Jimenez et al., 2008), poplar *Populus tremula* (Renaut et al., 2005), blueberry *Vaccinium corymbosum* (Levi et al., 1999), Satsuma mandarin *Citrus unshiu* (Hara et al., 1999), peach *Prunus persica* (Arora and Wisniewski, 1994), apple tree *Malus domestica* (Wisniewski et al., 2008), *Rhododendron catawbiense* (Wei et al., 2005; Peng et al., 2008), red osier dogwood *Cornus sericea* (Karlson et al., 2003a,b), pistachio *Pistacia vera* (Yakubov et al., 2005), and others.

## 10.2 DEHYDRINS AND PLANT STRESS RESPONSE

### 10.2.1 EXPRESSION OF DEHYDRINS UNDER ENVIRONMENTAL STRESS FACTORS

Dehydrin proteins can be found in small amounts in young plant organs grown under optimum growth conditions and exhibit rapid cell division or cell elongation, e.g., root tips, elongating stems, petioles, etc. (Nylander et al., 2001; Rorat et al., 2004). Analogous to other LEA proteins, dehydrins also accumulate in plant embryos in later stages of their development (embryo maturation and desiccation). Apart from these natural physiological processes, dehydrins become expressed when plants are exposed to various stress factors, which are accompanied by cellular dehydration. Thus, dehydrins can be induced by drought, osmotic stress, enhanced salinity, stresses associated with abscisic acid (ABA) signaling, low-temperature stresses (cold and frost), and also biotic stresses associated with water loss and jasmonic acid signaling such as wounding. All these stresses have a dehydration component. In addition, metal ion binding properties have been reported for some dehydrins (CuCOR15—Hara et al., 2005), which can thus function as chelators and seem to confer plant tolerance to heavy-metal stress (Xu et al., 2008). Dehydrins encoded by one plant genome are usually expressed in different plant tissues (organs) and in response to different developmental and environmental cues; see expression studies in *A. thaliana* by Nylander et al. (2001), Bies-Ethève et al. (2008), Hundertmark and Hincha (2008)—51 *Lea* genes, 10 of them dehydrins; in rice by Wang et al. (2007)—34 *Lea* genes, 8 of them dehydrins identified in Japonica rice Nipponbare; in barley (*Hordeum vulgare*) by Choi et al. (1999) or a more recent work by Tommasini et al. (2008)—13 dehydrin genes.

Under stress conditions, dehydrins accumulate in various compartments inside the cells—nucleus (PCA60 from peach—Wisniewski et al., 1999; WCS120 from common wheat—Houde et al., 1995; phosphorylated forms of maize RAB17 and DHN1—Godoy et al., 1994; Koag et al., 2003; phosphorylated TAS14 in salt-stressed tomato—Godoy et al., 1994; 24 kDa dehydrin in red osier dogwood (*Cornus sericea*)—Karlson et al., 2003a; AmDHN1a from gray mangrove (*Avicennia marina*)—Mehta et al., 2009), nucleolus and euchromatin (TAS14 in salt-stressed tomato (*Lycopersicon*

*esculentum*)—Godoy et al., 1994). Recently, Hara et al. (2009) have reported for CuCOR15, a histidine-rich dehydrin protein, Zn<sup>2+</sup>-dependent DNA and RNA binding affinity. Unlike Cys<sub>2</sub>His<sub>2</sub> zinc-finger transcription factors, the binding affinity of CuCOR15 is not sequence-specific. Thus, Hara et al. (2009) have proposed a general protective function for CuCOR15. Furthermore, dehydrins have been localized to semiautonomous organelles such as outer membrane of mitochondria (Borovskii et al., 2000, 2002; Hara et al., 2003; Carjuzaa et al., 2008), chloroplasts (PCA60 from peach (*Prunus persica*)—Wisniewski et al., 1999; *HaDhn1* transcripts in sunflower (*Helianthus annuus*)—Natali et al., 2007) as well as immature proplastids (Carjuzaa et al., 2008), storage protein bodies and starch-rich amyloplasts (24 kDa dehydrin from downy birch (*Betula pubescens*)—Rinne et al., 1999). Dehydrins have also been localized to various membranaceous structures such as endoplasmic reticulum (CAP85 from spinach—Neven et al., 1993), rough endoplasmic reticulum cisternae (Carjuzaa et al., 2008), vacuole (VCaB45 from celery—Heyen et al., 2002), membranes of lipid vesicles containing acidic phospholipids (maize DHN1—Koag et al., 2003), membranes of protein and lipid bodies (Egerton-Warburton et al., 1997), inner side of plasmalemma (WCOR410 from common wheat—Danyluk et al., 1998) or plasmodesmata of vascular cambium cells (24 kDa dehydrin in *Cornus sericea*—Karlson et al., 2003a). Abu-Abied et al. (2006) have detected *A. thaliana* ERD10 in association with actin stress fibers in transformed rat fibroblasts. They have also reported a protective function of GFP-ERD10 on actin cytoskeleton in latrunculin-treated leaves of *Nicotiana benthamiana*. Taken together, it can be stated that dehydrins are intracellular proteins induced by stresses resulting in cellular dehydration. Until now, dehydrins have not been detected in cell walls.

At tissue and organ level, dehydrins accumulate mainly in those tissues and organs which are exposed to rapid changes in water content, i.e., outer leaves of inflorescence buds, epidermis in herbs or bark in woody plants, stomatal guard cells (e.g., Rab18 from *A. thaliana*—Nylander et al., 2001; *HaDhn1* transcripts from sunflower *Helianthus annuus*—Natali et al., 2007), adventitious root primordia, root apices (e.g., Lti29/ERD10 and ERD14 in *A. thaliana*—Nylander et al., 2001), and vascular tissues. In vascular tissues, dehydrins usually accumulate in living cells in the vicinity of vascular elements, especially in xylem ray parenchyma cells and phloem ray parenchyma cells (Godoy et al., 1994; Bravo et al., 1999; Wisniewski et al., 1999, 2008; Yakubov et al., 2005; Natali et al., 2007; Yakovlev et al., 2008).

For some dehydrin genes, an alternative splicing was reported, e.g., *VvDHN-1a* and *VvDHN-1b* transcripts of *VvDHN1* gene in grapevine (*Vitis vinifera*) (Xiao and Nassuth, 2006), *AmDHN1* and *AmDHN1a* transcripts of a dehydrin gene in gray mangrove (*Avicennia marina*) (Mehta et al., 2009), or *OsLea7* and *OsLea8* genes in Japonica rice (*Oryza sativa* cv. *japonica*) (Wang et al., 2007). For some dehydrin proteins, two types of posttranslational modifications—phosphorylation and O-glycosylation—under stress conditions have been reported. While phosphorylation has been quite widely reported, especially for dehydrins with the S-segment, and several functions for phosphorylated dehydrin proteins have been proposed, O-glycosylation has been reported only for some dehydrins in blueberry and pistachio (Levi et al., 1999; Yakubov et al., 2005) and no specific functions for glycosylated forms of these proteins have been suggested. Phosphorylation of the S-segment by casein kinase II (CK2)-type kinases has been shown to be associated with dehydrin translocation from cytoplasm into nucleus (e.g., RAB17 in maize (*Zea mays*)—Godoy et al., 1994; Jensen et al., 1998; Riera et al., 2004; TAS14 in tomato (*Lycopersicon esculentum*)—Godoy et al., 1994; DHN-5 in durum wheat (*Triticum turgidum* ssp. *durum*)—Brini et al., 2007a; however, nuclear localization has also been reported for some dehydrins that lack the S-segment (e.g., wheat WCS120 or peach PCA60; Houde et al., 1995; Wisniewski et al., 1999). For *A. thaliana* acidic dehydrins COR47, ERD10, and ERD14 and for celery (*Apium graveolens*) vacuole-located dehydrin VCaB45, it has been reported by Alsheikh et al. (2003, 2005) and by Heyen et al. (2002), respectively, that phosphorylation is necessary for Ca<sup>2+</sup> binding properties of these proteins. Recently, *in vitro* phosphorylation has also been reported for K<sub>n</sub>-type dehydrin Lti30 from *A. thaliana* by Eriksson and Harryson (2009). The phosphorylation of K<sub>n</sub>-type dehydrins is provided by a different kinase than phosphorylation of dehydrins with an S-segment.

When dehydrin expression at transcript (mRNA) and protein level is compared, several differences can be found. Zhu et al. (2000) investigated expression of barley *Dhn5* gene at transcript and protein level in plants grown under field conditions and found out that either only transcript or only protein molecules can be present in the sample. Different dynamics of dehydrin transcript and protein accumulation during a time course of a stress treatment has also been described. For example, Ganeshan et al. (2008) compared wheat dehydrin (*Wcs120*, *Wcor410*) expression at transcript and protein levels during a long-term cold acclimation (CA) and found out that the peak in transcript accumulation precedes the peak in protein accumulation during the time course of CA treatment (2 days of CA versus 56 days of CA at transcript and protein levels, respectively).

Recently, dehydrin expression in various plant species and their functions under different stress conditions have been reviewed by Svensson et al. (2002), Allagulova et al. (2003), Rorat (2006), and specifically for cold stress by Kosová et al. (2007). In NCBI database (<http://www.ncbi.nlm.nih.gov/>), 1090 dehydrin protein sequences from 133 plant species were available in July, 2009. In the following paragraphs, expression of dehydrins and their specific functions in different plants under different stress conditions will be characterized according to the following scheme: First, a brief characteristics of each stress factor will be given. Second, signaling pathways which cooperate in induction of dehydrin expression under a given stress factor will be characterized. Third, examples of dehydrins expressed in various plant species under a given stress factor will be listed and their specific functions (if known) will be discussed.

## 10.2.2 DROUGHT STRESS, EVAPORATION

### 10.2.2.1 Physiological Aspects of Drought Stress

Drought is one of the major abiotic stress factors, which significantly limit plant growth and agronomic production in many areas worldwide. Drought, i.e., a shortage of rainfall, leads to the decrease in soil water potential (gravimetric soil water content), which is also often accompanied by a decrease in air relative humidity resulting in an enhanced rate of leaf transpiration. The decreased soil water potential draws water from ambient environment with higher water potential including plant cells. Plant acclimation to drought stress which tries to eliminate excessive water loss lies in osmotic adjustment, i.e., a decrease of cell water potential in order to diminish the difference in water potential between the plant cell and the ambient soil. Osmotic adjustment is associated with accumulation of low-molecular well-soluble metabolites collectively called compatible solutes (low-molecular saccharides, monosaccharides: glucose, fructose; disaccharides: sucrose, oligosaccharides raffinose, stachyose, and verbascose; sugar alcohols: mannitol, pinitol, sorbitol; quaternary ammonium compounds called betaines: alanine betaine, glycine betaine; imino acid proline; polyamines spermine, spermidine, putrescine) and with relatively high-molecular hydrophilic proteins inside the cells. Among hydrophilic proteins (hydrophilins), several LEA proteins including dehydrins accumulate to relatively high extents (amounts) in various plant cells during the process of osmotic adjustment. Osmotic adjustment lies in fact in the decrease of one major component of water potential—osmotic potential, which is determined by concentration (activity) of dissolved compounds in a solute (osmotic potential is defined as a negative value of osmotic pressure). Other components of cell water potential, i.e., pressure (or turgor) potential, which is determined by a hydrostatic pressure of cytosol against cell wall, gravitational potential, which is determined by position of water in gravitational field, and matrix potential, which is determined by adhesive forces of water-to-cell surfaces, are not significantly affected by accumulation of compatible solutes.

In soil water potential (relative air humidity) as well as in leaf water potential, diurnal changes have been observed, with maximum values before dawn and minimum values at midday (noon). It is becoming evident that these changes are mirrored in the expression of several drought-inducible hydrophilic proteins including dehydrins (e.g., Cellier et al., 2000).

### 10.2.2.2 Signaling Pathways Involved in Drought-Inducible Dehydrin Gene Expression

Drought-inducible dehydrins contain ABA-responsive elements (ABRE), C-repeat/drought-responsive/low-temperature-responsive elements (CRT/DRE/LTRE), myeloblastosis (MYB) and myelocytomatosis (MYC) regulatory elements in their promoter regions. Their expression is thus regulated by both ABA-dependent and ABA-independent signaling pathways. ABA-dependent signaling pathways include either bZIP transcription activators named ABFs or AREBs (ABRE-binding factors), which bind to ABRE elements, homologues of *A. thaliana* CBF4/DREB1D transcription activator, which bind to CRT/DRE/LTRE elements, and MYBFs and MYCFs, which bind to MYB and MYC promoter elements. ABA-independent signaling pathways include homologues of *A. thaliana* DREB2A and DREB2B transcription activators, which bind to CRT/DRE/LTRE elements (for review on stress signaling pathways and regulatory elements in the promoters of *Corl/Lea* genes, see, e.g., Bray, 1997; Zhu, 2002; Chinnusamy et al., 2004; Shinozaki and Yamaguchi-Shinozaki, 1997, 2000; Shinozaki et al., 2003; Yamaguchi-Shinozaki and Shinozaki, 2005, 2006).

### 10.2.2.3 Dehydrin Expression under Drought

#### 10.2.2.3.1 Dehydrin Expression in Mature Seeds under Drought

Dehydrins as LEA proteins accumulate in plant seeds which undergo desiccation during a physiological process of maturation drying. For example, Jiménez et al. (2008) and Kalembe et al. (2009) reported accumulation of dehydrins during desiccation of beech (*Fagus sylvatica*) embryos and seeds. It is well known that mature plant embryos in seeds that undergo desiccation during their maturation are tolerant to drought. The seeds that undergo maturation drying are called orthodox seeds (e.g., barley, beech, maize, or rice). In contrast, seeds of some species, e.g., tropical wetland plants such as gray mangrove (*Avicennia marina*), but also some temperate woody plants such as horse chestnut (*Aesculus hippocastanum*) or oak (*Quercus* sp.), do not undergo maturation drying. They remain metabolically active throughout embryo maturation and can germinate already before shedding from the parent plant. These seeds are called recalcitrant seeds. (To get more information about seed recalcitrance, see e.g., Berjak and Pammenter, 2008.) Some researchers have shown that these two physiologically different types of seeds—orthodox and recalcitrant—differ also in accumulation of LEA proteins including dehydrins. Farrant et al. (1992) have reported an absence of dehydrins in later stages of seed development in gray mangrove (*Avicennia marina*) recalcitrant seeds. Similarly, Han et al. (1997) have shown that the susceptibility to desiccation in recalcitrant seeds of *Trichilia dregeana* may be due to their inability to accumulate sufficient amounts of dehydrins, especially after the beginning of germination. In contrast to these studies, no differences in dehydrin levels were found between desiccation-tolerant orthodox seeds of rice (*Oryza sativa*) and recalcitrant seeds of *Zizania palustris* during germination (Bradford and Chandler, 1992). In young seedlings, an ABA-induced dehydrin expression was observed in tolerant *Cynanchum komarovii* plantlets upon severe dehydration stress (Yang et al., 2007). It is well known that dehydrin accumulation in plant embryos and seedlings is regulated by ABA. However, dehydrin *Mat1* in soybean (*Glycine max*) seedlings is induced by dehydration, but not by ABA—that is quite unusual for dehydrin expressed under drought conditions (Whitsitt et al., 1997).

#### 10.2.2.3.2 Dehydrin Expression in Plants under Drought

Dehydrins play an important role not only in maturing plant embryos, but also in later stages of plant development during plant response to stress factors associated with cellular desiccation. According to tolerance to cellular desiccation, plants can be divided into two major groups: poikilohydric plants and homoiohydric plants. Poikilohydric plants are generally much more tolerant to cellular dehydration than homoiohydric plants due to small vacuoles and relatively low vacuole to cytoplasm ratio when compared with homoiohydric plants (about poikilohydry and homoiohydric in plants, see review by Proctor and Tuba, 2002).

Poikilohydric plants include predominantly various desiccation-tolerant seedless plants such as desiccation-tolerant mosses, lycopods from the genus *Selaginella* and ferns from the genus

*Polypodium*. However, they also include a few desiccation-tolerant angiosperms which have cells with small vacuoles and can recover after up to 95% (practically total) water loss. These plants are sometimes called “resurrection plants” —e.g., *Craterostigma plantagineum*, *Ramonda serbica*, etc. (Scott, 2000).

In desiccation-tolerant moss *Tortula ruralis*, dehydrin Tr288 with several repeats of K-segments in its C-terminal domain was detected by Velten and Oliver (2001). These researchers found out that during dehydration, particles of Tr288 mRNP accumulate in desiccating cell cytoplasm. The researchers have hypothesized that Tr288 protein could become expressed (synthesized) during subsequent cellular rehydration rather than during dehydration. Therefore, Tr288 can be better characterized as a “rehydrin.” Dehydrins have also been described in *Polypodium virginianum* (Reynolds and Bewley, 1993) and in *Selaginella lepidophylla* (Iturriaga et al., 2006). In *Craterostigma plantagineum*, an *in vitro* unfolded dehydrin Dsp16 has been studied (Piatkowski et al., 1990; Lisse et al., 1996).

Dehydrins also accumulate in homoiohydric plants when they are exposed (subjected) to drought stress. Several studies have shown that dehydrin accumulation during plant vegetative growth correlates with their drought tolerance. Labhili et al. (1995) and Brini et al. (2007a) have shown that dehydrin accumulation confers tolerance to drought and salt stress in durum wheat (*Triticum turgidum* ssp. *durum*). The latter authors have also shown nuclear localization of a stress-inducible dehydrin protein DHN-5 and they have also detected differences in phosphorylation pattern of DHN-5 between two Tunisian cultivars of durum wheat. A sensitive cultivar revealed only a low level of dehydrin phosphorylation while a highly tolerant cultivar exhibited high level of dehydrin phosphorylation. DHN-5 from durum wheat is  $Y_nSK_n$  type dehydrin sequentially similar to bread wheat Rab15, barley DHN3, DHN4, and DHN9, or maize Rab17. In wild barley (*Hordeum vulgare* ssp. *spontaneum*), Suprunova et al. (2004) have observed expression of several  $Y_nSK_n$ -type dehydrins (especially *Dhn1* and *Dhn6*, but also *Dhn3* and *Dhn9*) associated with enhanced drought tolerance.

Similarly, Pelah et al. (1997) have observed a positive relationship between dehydrin accumulation and drought tolerance in aspen (*Populus tremula*). Analogously, Tabaei-Aghdaei et al. (2000) compared dehydrin protein accumulation in crown tissues of two wheatgrass species revealing different levels of drought tolerance—a drought-tolerant *Agropyron desertorum* and a less tolerant *Lophopyrum elongatum*—under drought stress (6 days without watering) and the researchers detected much higher levels of dehydrin polypeptides in the drought-tolerant *A. desertorum* than in *L. elongatum*. Volaire (2002) found association of 22–24 kDa dehydrin accumulation with enhanced tolerance to drought and acquisition of summer dormancy in leaf bases of two contrasting varieties of cocksfoot (*Dactylis glomerata*), one of Mediterranean Moroccan origin (a drought-tolerant variety) and the other of oceanic French origin (a drought-sensitive variety). In contrast, no differences were observed at transcript level (Voltaire et al., 1998). These results suggest an existence of different regulatory mechanisms between *Dactylis glomerata* varieties with different drought tolerance at posttranscriptional level.

Cellier et al. (1998) have observed higher transcript levels of dehydrin genes *HaDhn1* and *HaDhn2* in a drought-tolerant cultivar of sunflower (*Helianthus annuus*) when compared with a drought-sensitive one. The accumulation of *HaDhn1* and *HaDhn2* transcripts correlates with plant leaf water potential when the cultivars were compared under the same gravimetric soil water content. Cellier et al. (2000) have also observed diurnal changes in *HaDhn1* gene expression in sunflower plants subjected to drought with a maximum *HaDhn1* expression at midday (noon) which mirrored the changes in leaf water potential. In contrast, *HaDhn2* gene showed no significant diurnal changes in its expression pattern.

### 10.2.3 SALINITY AND OSMOTIC STRESS

#### 10.2.3.1 Brief Characteristics of Salinity Stress

High salinity means enhanced salt ion concentrations in soil water, which is taken up by plants. Plants as well as other organisms actively regulate cytoplasmic (intracellular) ion concentrations, especially concentrations of  $Na^+$ ,  $K^+$ ,  $Ca^{2+}$ , and  $Cl^-$  and phosphate ions via ATP-dependent ion

channels (pumps) in plasmalemma, tonoplast, and membranes of endoplasmic reticulum. According to tolerance to enhanced cytoplasmic ion concentrations, plants can generally be divided into glycophytes, which do not tolerate enhanced (increased) cytoplasmic ion concentrations, and halophytes, which tolerate (or even require) enhanced cytoplasmic ion concentrations. Glycophytes include most economically important plant crop species such as barley, wheat, maize, or rice, but also a model plant *Arabidopsis thaliana*. Halophytes include mostly plants living on sea coasts where they are in permanent contact with salt water—e.g., *Salsola kali*, *Salicornia*, or *Arabidopsis* salt-tolerant relative *Thellungiella salsuginea* which is used as a model plant for studies of plant salt-tolerance mechanisms (Amtmann, 2009).

In case of glycophytes, high ion concentrations in soil water result in decreased osmotic potential of soil solution relative to cytoplasmic osmotic potential and this difference triggers water from plant cell cytoplasm. Thus, high salinity has a similar effect on glycophytes as a drought stress. Therefore, compatible solutes such as proline, sugar alcohols, polyamines, low molecular saccharides (products of starch degradation—maltose, glucose) as well as hydrophilic proteins (dehydrins) accumulate in cell cytoplasm upon salt stress.

#### 10.2.3.2 Salt-Inducible Dehydrins

Dehydrin expression under salt stress has predominantly been studied in several economically important glycophytes whose production is strongly reduced by enhanced soil salinity. Only a few studies have been carried out on relatively salt-tolerant plant species such as *Avicennia marina* or *Lophopyrum elongatum* (Tabaei-Aghdai et al., 2000; Mehta et al., 2009).

Godoy et al. (1994) have studied tissue and subcellular localization of dehydrin TAS14 in salt-stressed tomato (*Lycopersicon esculentum*) and found its major accumulation in nucleus and nucleolus in the cells of xylem ray parenchyma neighboring the vascular tissue. The protein accumulated especially in stems and leaves and only a transient accumulation was detected in roots. Godoy et al. (1994) also found out that TAS14 is a phosphoprotein *in vivo* and that it could be phosphorylated by both casein kinase II and cAMP-dependent protein kinase *in vitro*.

Moons et al. (1995) have detected several dehydrins and LEA 3 proteins of various molecular mass (dehydrins of 24 kDa, 35 kDa, and 50 kDa) in roots of salt-tolerant Indica rice (*Oryza sativa* cv. indica) varieties Pokkali and Nona Bokra in response to salt stress (50 mM NaCl) and exogenous ABA treatment (20  $\mu$ M or 100  $\mu$ M ABA; pH 5.6). Similarly, Gulick and Dvořák (1992) have detected expression of one dehydrin in roots of salt-tolerant wheatgrass species *Lophopyrum elongatum* in response to salt stress (250 mM NaCl). Masmoudi et al. (2001) found differences in the expression of *DHN-5* gene (*Tdsi-5* cDNA clone) in roots and leaves of two cultivars of durum wheat (*Triticum turgidum* ssp. *durum*) with marked differences in their salt tolerance when the seedling plants were exposed to salt stress (compost soil supplemented with 200 mM NaCl). Later, Brini et al. (2007a) also reported differences in DHN-5 phosphorylation pattern between the same cultivars exposed to the same type of salt stress with large portions of phosphorylated forms of DHN-5 in a tolerant cultivar and much less amounts of phosphorylated DHN-5 in a salt-sensitive one. In contrast, Tabaei-Aghdai et al. (2000) detected no significant differences in the accumulation of dehydrin polypeptides in crown tissues of two wheatgrass species—a salt-tolerant *Lophopyrum elongatum* and a less tolerant *Agropyron desertorum*—when the plants were subjected to a high salt stress (daily exposure to 75 or 150 mM NaCl for 6 days).

Accumulation of dehydrins in response to salt and osmotic stress has also been reported in woody plants. In poplar *Populus euramericana*, enhanced levels of dehydrin transcript of *PeuDhn1* (an SK<sub>n</sub> type dehydrin) were observed by Caruso et al. (2002) in response to salt stress (1.36 g L<sup>-1</sup> NaCl) or osmotic stress (hydroponic cultivation with 50 g L<sup>-1</sup> PEG 6,000). The level of expression of this gene seemed to correlate with leaf osmotic potential. Mehta et al. (2009) found a rapid up-regulation of *AmDHN1* gene (a YSK<sub>n</sub> type dehydrin) by 500 mM NaCl in gray mangrove (*Avicennia marina*), a pantropical mangrove species inhabiting coastal locations with excess salinity.

## 10.2.4 DEHYDRINS AND LOW-TEMPERATURE STRESS (COLD AND FROST)

### 10.2.4.1 Brief Characteristics of Low-Temperature Stresses (Cold and Frost)

Biennial and perennial plants inhabiting locations in higher latitudes and/or altitudes have to cope with relatively long periods of low temperatures (cold and frost) during winter. Annuals that survive winter as seeds often have to resist low temperatures as seedlings in early spring. In higher latitudes, periods of low temperatures are associated with short-day photoperiods, which are sensed by plants and function as a signal which precedes low-temperature stress (e.g., in initiation of winter dormancy in woody perennials). Plant winter hardiness has several components, e.g., desiccation tolerance, tolerance to the effects of snow cover, tolerance to flooding or repeated freeze-thaw cycles. Frost tolerance, i.e., plant ability to withstand adverse effects of low-temperature stress (especially effects of subzero temperatures, i.e., frost), presents a major component of plant winter hardiness. According to tolerance to low temperatures, plants can generally be divided into three groups: (1) chilling-sensitive plants which are susceptible to low above-zero temperatures (chilling: usually defined as a range between 0°C and +12°C (+15°C)—these plants include many crops of tropical and subtropical origin, such as cucumber (*Cucumis sativus*), tomato (*Lycopersicon esculentum*), maize (*Zea mays*), rice (*Oryza sativa*), cotton (*Gossypium hirsutum*), tropical legume crops such as cowpea (*Vigna unguiculata*) and chickpea (*Cicer arietinum*); (2) chilling-tolerant, but frost-sensitive plants, which are tolerant to chilling, but severely damaged by frost; and (3) frost-tolerant plants that can survive freezing temperatures in vegetative stage—these include especially winter varieties of *Triticeae* cereals, i.e., winter barley (*Hordeum vulgare*), winter wheat (*Triticum aestivum*), or winter rye (*Secale cereale*) (Levitt, 1980; Sakai and Larcher, 1987).

However, in most frost-tolerant plants, frost tolerance is usually not a constitutive trait, but it can be induced by low, but above-zero temperatures (cold). This adaptive process is called cold acclimation (CA). Different aspects of CA are reviewed in Levitt (1980), Sakai and Larcher (1987), Guy (1990), Pearce (1999), Thomashow (1999), Xin and Browse (2000), and others. CA process leads to enhancement of plant winter hardiness and frost tolerance. Frost, i.e., freezing of water—formation and growth of ice crystal nuclei—is accompanied by cellular dehydration. Therefore, plant cold acclimation leads to adaptive responses in order to minimize adverse effects of cellular dehydration. These responses are associated with accumulation of compatible solutes and hydrophilic proteins including dehydrins in various intracellular compartments.

### 10.2.4.2 Signaling Pathways Involved in Dehydrin Expression under Cold and Frost

Similar to drought stress, dehydrins expressed under cold are regulated by both ABA-dependent and ABA-independent regulatory pathways. ABA-dependent pathways include ABRE regulatory elements in dehydrin promoters, which function as binding sites for bZIP ABRE-binding transcription factors (AREBs or ABFs). The main ABA-independent cold-inducible signaling pathway is the CBF/DREB1 pathway. The CBF/DREB1 transcription activators possess AP2 DNA-binding domain flanked by two unique sequence motifs (called signature motifs), which can bind to CRT/DRE/LTRE elements in dehydrin (and other *Cor* gene) promoter region. The up-regulation of several *Cor* gene expression as a consequence of CBF gene overexpression was first reported by Jaglo-Ottosen et al. (1998) in *A. thaliana*. In the genome of *A. thaliana*, three predominantly cold-inducible *CBF/DREB1* genes—*CBF1/DREB1B*, *CBF2/DREB1C*, and *CBF3/DREB1A*—were characterized which are tandemly arranged on chromosome four. (The fourth member of *CBF/DREB1* gene family—*CBF4/DREB1D*—is predominantly drought- and ABA-inducible—Haake et al., 2002.) Currently, homologues of *A. thaliana CBF/DREB1* genes have been sequenced and further characterized in several other species, especially in cereals from the tribe *Triticeae* (e.g., Skinner et al., 2005, 2006; Miller et al., 2006; Badawi et al., 2007; Francia et al., 2007) where the majority of *CBF* genes was mapped to *Frost-resistance 2* (*Fr-2*) locus, previously characterized as a major QTL determining frost tolerance level and *Cor* gene expression in *Triticeae* (e.g., Vágújfalvi et al., 2000, 2003). The conformation of the AP2 domain appears to be essential for binding of the CBFs to CRT/DRE/LTRE promoter

elements and activation of *Cor* gene expression. Recently, Knox et al. (2008) have described an allelic variation in *TmCBF12* gene located to *Fr-A<sup>m</sup>2* locus in einkorn wheat (*Triticum monococcum*). A freezing-sensitive line of *T. monococcum* possesses *TmCBF12* allele with a deletion of a few aa residues in the AP2 domain of the protein. As a consequence, *TmCBF12* cannot bind to CRT/DRE/LTRE elements in *Cor* gene promoters.

Recently, Bassett et al. (2009) have reported conformational transitions in the promoter regions of cold-inducible peach dehydrin genes *PpDhn1* and *PpDhn3*. They have hypothesized that these cold-inducible conformational transitions may strongly influence cold-inducible expression of these dehydrins.

#### 10.2.4.3 Low Temperature-Inducible Dehydrins and Their Features

Low temperature-induced dehydrins exhibit various protective functions: cryoprotective function, antifreeze activity, cold-inducible phosphorylation, metal ion binding, and ROS scavenging activities.

A cryoprotective activity has been reported for several cold-inducible dehydrins, e.g., COR85 from spinach (Kazuoka and Oeda, 1994), WCS120 from common wheat (Houde et al., 1995), PCA60 from peach (Wisniewski et al., 1999), CuCOR19 from *Citrus unshiu* (Hara et al., 2001), DHN5 from barley (Bravo et al., 2003). When LDH assay is used, these proteins exhibit significant cryoprotective activity, which is sometimes stronger than a protective activity of several widely used sugar cryoprotectants such as sucrose or cryoprotective proteins such as bovine serum albumin (BSA). A protective effect on the activity of  $\alpha$ -amylase (EC 3.2.1.1) under cold has been reported by Rinne et al. (1999) for a 24 kDa dehydrin from downy birch (*Betula pubescens*).

An antifreeze activity, i.e., modification of ice crystal growth and thermal hysteresis during freezing of protein aqueous solution was first reported for PCA60, a Y<sub>2</sub>K<sub>9</sub> dehydrin isolated from bark tissue of peach (*Prunus persica*) (Arora and Wisniewski, 1994; Wisniewski et al., 1999) and encoded by *PpDhn1* gene. At high concentrations (micromolar to millimolar) of antifreeze proteins, ice crystal growth is inhibited along the *a*-axes while the *c*-axis becomes the preferred direction of growth. As a consequence, instead of flat round crystals formed by ice crystal nuclei in pure water, ice crystals of a shape of hexagonal bipyramids are formed in aqueous solutions containing proteins with an antifreeze activity. Moreover, the proteins with an antifreeze activity also decrease the freezing point of aqueous solutions in which they are dissolved; this phenomenon is called thermal hysteresis. In plants, antifreeze activity was first reported in 1992 for a specific group of proteins named antifreeze proteins (AFPs) (Griffith et al., 1992). PCA60 thus shares this function with AFPs, which also accumulate in the bark of woody perennials during winter dormancy (for review on AFPs, see e.g., Griffith and Yaish, 2004). Unlike dehydrins, AFPs are apoplastic proteins that accumulate in intercellular spaces where they inhibit growth and recrystallization of ice. Recently, a boiling-stable antifreeze protein revealing a sequence homology to dehydrins (containing several lysine-rich sequences and a Y-segment) was isolated from cold-acclimated bark tissue of *Forsythia suspensa* (Simpson et al., 2005).

Cold-induced phosphorylation of the S-segment has been reported for acidic SK<sub>n</sub>-type dehydrins COR47, ERD10 and ERD14 in *A. thaliana* (Alsheikh et al., 2003, 2005). When phosphorylated, these proteins can bind Ca<sup>2+</sup> ions, and Alsheikh et al. have speculated that they may act as calcium buffers or sugar chaperones under these conditions. It is also well known that Ca<sup>2+</sup> ions act as second messengers in cold-inducible signaling pathways.

Radical-scavenging and metal ion binding properties of dehydrin proteins have already been discussed in Section 10.1.3.3.

##### 10.2.4.3.1 Chilling-Induced Dehydrin Expression in Mature Seeds

An increase in dehydrin transcript or protein level has also been observed in seeds exposed to chilling; e.g., *FsDhn1* gene in European beech (*Fagus sylvatica*; Jiménez et al., 2008). These researchers have also found out that the expression of *FsDhn1* gene in beech seeds is strongly up-regulated

by ABA treatment. Ismail et al. (1999b) have reported for an extremely chilling-sensitive tropical legume crop *Vigna unguiculata* that seeds of a relatively chilling-tolerant line 1393-2-11 contained DHN1 (Y<sub>2</sub>K-type), which positively correlated with seedling emergence under mild cold conditions (14°C), while the DHN1 was absent in genetically related, but chilling-sensitive line 1393-2-1. Yao et al. (2005) have shown that expression of dehydrin genes *BnDHN1* and *BjDHN1* (both homologous Y<sub>3</sub>SK<sub>2</sub> dehydrins) in cold-treated seeds of *Brassica napus* and *Brassica juncea*, respectively, enhances plant cold tolerance during seedling emergence. These findings are analogous to the situation in *Arabidopsis thaliana* where RAB18 protein (also Y<sub>2</sub>SK<sub>2</sub> dehydrin) is known to accumulate in mature seeds and to confer seedling tolerance to cold stress (Lång and Palva, 1992; Nylander et al., 2001; Hundertmark and Hinch, 2008).

#### 10.2.4.3.2 Dehydrin Expression in Plants upon Cold

In many plants, accumulation of dehydrin transcripts and/or proteins has been observed during cold acclimation process (CA), which often precedes frost in nature. During CA, dehydrin accumulation was reported for various intracellular compartments, e.g., plasmalemma in case of WCOR410 in common wheat *Triticum aestivum* (Danyluk et al., 1998), endoplasmic reticulum in case of CAP85 in spinach (Neven et al., 1993), nucleus in case of WCS120 in common wheat (Houde et al., 1995) or PCA60 in peach (*Prunus persica*), chloroplasts in case of peach PCA60 (Wisniewski et al., 1999), amyloplasts in case of 24 kDa dehydrin from downy birch *Betula pubescens* (Rinne et al., 1999), mitochondria in case of dehydrins in wheat (Borovskii et al., 2000, 2002). At tissue level, dehydrin accumulation under cold stress was observed predominantly in epidermal cells and in xylem ray parenchyma cells, i.e., in tissues in neighborhood of large extracellular spaces where ice crystals can be formed during freezing. This tissue distribution was observed for cold-inducible dehydrins in both dicotyledons and monocotyledons for *Arabidopsis thaliana* (Nylander et al., 2001) as well as for barley (Bravo et al., 1999). In citrus trees, some dehydrins have been reported to accumulate in fruit flavedo tissue after a rapid temperature change (chilling after a brief heat shock). This pattern of dehydrin induction was reported for CsDHN in orange *Citrus sinensis* and for COR15 and CpDHN in grapefruit *Citrus paradisi* (Porat et al., 2002, 2004).

Cold-inducible dehydrins have been studied in many herbaceous and woody plants. Currently, the most studied plant is *Arabidopsis thaliana* in which a total of 51 *Lea* genes have been identified (Hundertmark and Hinch, 2008), 10 of them represent dehydrins (Nylander et al., 2001). For five dehydrins—*Cor47*, *Erd10/Lti29*, *Erd14*, *Lti30/Xero2*, and *Rab18*, a cold-inducible expression has been reported (Nylander et al., 2001). Three cold-inducible dehydrin genes, *Cor47*, *Erd10/Lti29*, and *Erd14* encode acidic SK<sub>n</sub>-type proteins while *Lti30* encodes a K<sub>n</sub>-type protein and *Rab18* encodes predominantly drought- and ABA-inducible (but also cold-inducible) basic Y<sub>n</sub>SK<sub>n</sub>-type protein. While the first four dehydrin proteins accumulate only in various non-seed tissues (predominantly vascular tissues, but also root tips in case of ERD10, or anthers in case of Lti30), RAB18 accumulates also in mature embryos.

A positive effect of dehydrin transcript and/or protein accumulation upon CA conditions on plant tolerance to cold and/or frost has been reported for many cold-inducible dehydrins in various plant species, e.g., for CpDHN1 in *Cicer pinnatifidum*, which is a cold-tolerant wild relative of chickpea *Cicer arietinum* (Bhattarai and Fettig, 2005), CAS15 in alfalfa *Medicago sativa* (Monroy et al., 1993), CAS15 and CAS18 dehydrins in cell suspension culture of alfalfa *Medicago falcata* (Wolfrain et al., 1993), WCS120 in common wheat *Triticum aestivum* (Houde et al., 1992a,b; Vítámvás et al., 2007), DHN5 in barley (Close et al., 1995; Kosová et al., 2008), etc.

#### 10.2.4.3.3 Dehydrin Expression in Woody Plants during Winter Dormancy

In woody perennials, dehydrins accumulate predominantly during winter dormancy. Winter dormancy is a complex physiological process that is aimed at the enhancement of winter hardiness (overwintering) in woody perennials and that is induced by low temperatures (both cold and frost) and short-day photoperiods during autumn. Processes of cold acclimation and winter dormancy in

woody plants were reviewed recently by Welling and Palva (2006). The process of winter dormancy acquisition is associated with several changes in plant metabolism including accumulation of various hydrophilic proteins (dehydrins).

Wisniewski et al. (2008) studied expression of dehydrin EST homologous to *Arabidopsis Xero2* gene in young apple trees (*Malus × domestica* cv. “Royal Gala”) under cold (24 h at 5°C) and found a high increase in dehydrin expression in bark and xylem tissues and only a mild enhancement in leaves. Therefore, it can be concluded that dehydrin expression in woody plants subjected to cold is tissue-specific. In bark tissues, several hydrophilic proteins (e.g., bark storage proteins, 70 kDa heat-shock proteins, dehydrins) accumulate under cold acclimation (e.g., Wetzel et al., 1989; Wisniewski et al., 1996; Pagter et al., 2008).

For several dehydrins accumulating during winter dormancy, induction by short-day photoperiods has been reported—e.g., *BpLti36* gene in silver birch (*Betula pendula*) (Puhakainen et al., 2004a), *BpuDHN1* (a dominant effect of SD induction) and *BpuDHN2* (only a small effect of SD induction) genes in pubescent (downy) birch (*Betula pubescens*) (Welling et al., 2004), *BbDhn7* gene in blueberry (*Vaccinium corymbosum*) (Dhanaraj et al., 2005), spliced forms of *DHN-1* genes in *Vitis riparia* and *Vitis vinifera* (Xiao and Nassuth, 2006), 24 kDa dehydrin in red osier dogwood (*Cornus sericea*) (Karlson et al., 2003b), or *PaDhn1* and *PaDhn6* genes in Norway spruce (*Picea abies*) (Yakovlev et al., 2008). Signaling pathways involved in short-day regulated dehydrin gene expression remain to be characterized although Welling and Palva (2008) have recently identified four homologues of *CBF* genes in silver birch, named *BpCBF1* to *BpCBF4*, involved in regulation of *BpLti36* gene expression.

Dehydrins which accumulate in bark tissues during winter dormancy often exhibit protective functions. For example, 24 kDa dehydrin from *Betula pubescens*, which accumulates in the vicinity of storage protein bodies and starch-rich amyloplasts under cold, exhibits protective effect on  $\alpha$ -amylase (EC 3.2.1.1.) enzymatic activity *in vitro*. Similarly, dehydrin RcDhn5 from *Rhododendron catawbiense* can protect LDH activity *in vitro* (Peng et al., 2008).

Dehydrins also accumulate in buds during winter dormancy. Yakubov et al. (2005) detected dehydrin protein, PV-DHN, in the outer leaves of inflorescence buds in pistachio (*Pistacia vera*), grown in Negev desert highlands, during December and January. Yakovlev et al. (2008) studied changes in dehydrin gene expression in buds of Norway spruce (*Picea abies*) during bud winter dormancy and subsequent flushing. During bud flushing, expression of some *PaDhn* genes (*PaDhn1*, *PaDhn4.6*, *PaDhn5*, *PaDhn6*, *PaDhn2*, and *PaDhn3*) declines while expression of other *PaDhn* genes (*PaCAP1*, *PaDhn4.2*, and *PaDhn7*) does not change significantly. These results can suggest that dehydrins from the first group may be related to bud winter hardiness while dehydrins from the second group may have general protective functions.

### 10.2.5 DEHYDRINS AND HEAVY-METAL STRESS

Recently, metal ion binding properties have been found in some dehydrins, e.g., in CuCOR15 from *Citrus unshiu* (Hara et al., 2005). Dehydrins may thus function as chelators analogous to metallothioneins and phytochelatins, although different amino acid residues are involved in metal ion binding. Instead of cysteine thiol groups responsible for metal ion binding in metallothioneins and phytochelatins, histidine was reported to bind several metal ions—Co<sup>2+</sup>; Cu<sup>2+</sup>; Fe<sup>2+</sup>; Fe<sup>3+</sup>; Ni<sup>2+</sup>; Zn<sup>2+</sup> in CuCOR15. Recently, some papers showing a positive effect of dehydrin expression on plant heavy-metal tolerance have been published. Xu et al. (2008) found out that the expression of BjDHN2 and BjDHN3 proteins from *Brassica juncea* in transgenic tobacco resulted in plants which accumulated higher concentrations of Cd<sup>2+</sup> and Zn<sup>2+</sup> in their root system with respect to wild-type plants when they were exposed to stress conditions (100  $\mu$ M CdCl<sub>2</sub> or 200  $\mu$ M ZnCl<sub>2</sub> for 10 days) and thus the transformants exhibited higher tolerance to heavy-metal stress. In contrast, *Brassica juncea* plants with inhibited expression of *BjDHN3* (via expression of antisense *BjDHN3* mRNA) revealed increased electrolyte leakage and reduced accumulation of Cd<sup>2+</sup> and Zn<sup>2+</sup>, which

indicates that they were not able to cope with heavy-metal stress. Zhang et al. (2006) have observed increased expression of an SK<sub>n</sub>-type dehydrin PvSR3 transcripts in roots of bean (*Phaseolus vulgaris*) in response to various heavy metals including cadmium and mercury (in the form of 0.2% w/v CdCl<sub>2</sub> or HgCl<sub>2</sub>). Tamás et al. (2006) have observed enhanced expression of *Dhn4* in barley roots in response to aluminum (10 mM AlCl<sub>3</sub> pH 4.0).

Recently, Hara et al. (2009) have reported for CuCOR15 that increased concentrations of Zn<sup>2+</sup> lead to the interaction of this histidine-rich dehydrin with DNA and RNA. They have shown that the CuCOR15 nucleic-acid binding affinity is not sequence-specific; thus, they have hypothesized that binding of CuCOR15 to nucleic acids may have general protective functions under stress conditions.

### 10.2.6 DEHYDRINS AND BIOTIC STRESSES (WOUNDING)

Wounding, i.e., mechanical damage of plant tissues by herbivores or (sucking apparatus of) insects is a common biotic stress that most plants have to face every day. Wounding is associated with cellular damage that leads to water loss. Thus, wounding can also be regarded as a dehydration stress. In wounding stress signaling, salicylic acid (a derivative of 3-hydroxy-3-phenylpropanoic acid), jasmonic acid (a derivative of 12-oxo-*cis,cis*-10,15-phytodienoic acid), and its methyl ester methyl jasmonate play important roles.

For several dehydrins, e.g., CpDHN1 (Y<sub>2</sub>K dehydrin) from *Cicer pinnatifidum* (Bhattarai and Fettig, 2005) or for PgDHN1 (S<sub>8</sub>K<sub>4</sub> dehydrin) from white spruce *Picea glauca* (Richard et al., 2000), induction of gene expression by jasmonic acid and methyl jasmonate was reported. Rouse et al. (1996) carried out a promoter analysis of *A thaliana* cold-inducible K<sub>n</sub>-type dehydrin gene *Lti30* (*Xero 2*) using GUS reporter gene and they concluded that the *Lti30* promoter also revealed induction by wounding (damage of plant roots by forceps) among other treatments. In *Boea crassifolia*, expression of dehydrin *BcDh2* is induced upon wounding via salicylic acid and methyl jasmonate signals (Shen et al., 2004). Recently, Sun et al. (2009) have observed a positive effect of low concentrations of exogenous salicylic acid (up to 0.25 mM) on the expression of drought-inducible dehydrins in barley seedlings subjected to drought stress. In contrast, higher concentrations of salicylic acid (0.25–0.50 mM) have led to the decrease of dehydrin expression under the same growth conditions (water stress). Dehydrins may also play an important role in plant-defense mechanisms. Turco et al. (2004) have reported expression of several dehydrin proteins in drought-tolerant oak species *Quercus ilex* in response to infection with *Phytophthora cinnamomi*.

## 10.3 POSSIBILITIES OF THE USE OF DEHYDRINS FOR IMPROVEMENT OF PLANT TOLERANCE TO STRESS

Along with increasing knowledge of dehydrin protective functions in plant acclimation to various stress factors, attempts to exploit dehydrins for improvement of stress tolerance of economically important plants, especially crops, are becoming quite often recently. These studies include both transgenic techniques (expression of a given dehydrin gene in other organism or simply a modification of a dehydrin promoter sequence in order to enhance dehydrin gene expression) as well as selection of crop varieties with enhanced level of dehydrin expression, which often (but not always) correlates with enhanced level of stress tolerance.

### 10.3.1 TRANSGENIC STUDIES

Several transgenic studies have proven to have a positive effect of dehydrin gene expression and (or) dehydrin protein accumulation on plant stress tolerance. Studies carried out by Saavedra et al. (2006) on the moss *Physcomitrella patens*, which serves as a model organism due to the unique possibility to “knock-out” (make nonfunctional, disrupt) its genes via homologous recombination, have

shown that a *P. patens* knock-out mutant, which has its only dehydrin gene, *PpdhnA*, disrupted, reveals an impaired ability to recover after salt and osmotic stress (treatment either with 0.5 M NaCl or 0.9 M mannitol for 14 days).

In contrast, overexpression of several dehydrin genes under CaMV 35S promoter (constructs pT9 containing *Cor47* and *Rab18* genes and pT10 containing *Lti29* (= *Erd10*) and *Lti30* genes) in *A. thaliana* led to enhanced plant tolerance to cold stress (Puhakainen et al., 2004b). Analogously, Peng et al. (2008) have isolated *RcDHN5* gene (an SK<sub>2</sub> acidic dehydrin) from frost-tolerant *Rhododendron catawbiense* and they have shown that its expression in *A. thaliana* led to the enhancement of frost tolerance. Similarly, Yin et al. (2006) concluded that expression of DHN24 protein from wild potato *Solanum soganandinum* in cucumber (*Cucumis sativus*) led to enhancement of frost tolerance under cold (4°C). Similarly, studies that used a dehydrin transgene expressed in a stress-sensitive plant have reported enhanced tolerance to stress in the transformed plant. For example, Hara et al. (2003) have reported that expression of CuCOR19 from *Citrus unshiu* in tobacco mitochondria led to reduced lipid peroxidation, Houde et al. (2004) have found out that expression of WCOR410 from common wheat in strawberry led to the enhancement of strawberry frost tolerance. Kaye et al. (1998) have found out that tobacco plants expressing spinach CAP85 and CAP160 proteins revealed a lower level of electrolyte leakage after a frost test, which indicates a reduction of freezing injury in the transformants.

Brini et al. (2007b) have observed that expression of DHN-5 protein from durum wheat (*Triticum turgidum* ssp. *durum*) in *A. thaliana* led to the increase in *A. thaliana* salt and osmotic stress tolerance. RoyChoudhury et al. (2007) observed enhanced tolerance to drought and salt stress in tobacco plants transformed with *Rab16A* (= *Rab21*) gene from salt-tolerant indica rice variety Pokkali. The transformed plants exhibited reduced levels of H<sub>2</sub>O<sub>2</sub> and lipid peroxidation as well as lower accumulation of Na<sup>+</sup> and greater accumulation of K<sup>+</sup> when subjected to severe salt stress (200 mM NaCl). Similarly, Cheng et al. (2002) have shown that overexpression of wheat dehydrin PMA80 and wheat LEA I protein PMA1959 enhances rice tolerance to drought and salt stress. Figueras et al. (2004) have reported a positive effect of overexpression of maize Rab17 in *A. thaliana* on osmotic stress tolerance of the transformants. Park et al. (2006) have observed that *Arabidopsis* plants transformed with barley *Dhn3* and *Dhn4* genes stayed green and viable on a GM medium with 500 mM mannitol while *Arabidopsis* wild-type plants died under the same conditions. In contrast, Iturriaga et al. (1992) have not recorded any improvement of drought tolerance determined by ion leakage tests of transgenic tobacco plants expressing several LEA proteins including dehydrins from desiccation-tolerant *Craterostigma plantagineum* when the transformants' leaf discs were subjected to 30% PEG 6,000 solution.

Xu et al. (2008) found out that expression of BjDHN2 and BjDHN3 proteins from *Brassica juncea* in transgenic tobacco resulted in plants which could accumulate higher concentrations of Cd<sup>2+</sup> and Zn<sup>2+</sup> in their root system with respect to wild-type plants when they are exposed to stress conditions (100 µM CdCl<sub>2</sub> or 200 µM ZnCl<sub>2</sub> for 10 days) and thus the transformants exhibit higher tolerance to heavy-metal stress. In contrast, *Brassica juncea* plants with inhibited expression of *BjDHN3* (via expression of antisense *BjDHN3* mRNA) revealed increased electrolyte leakage and reduced accumulation Cd<sup>2+</sup> and Zn<sup>2+</sup>, which indicates that they were not able to cope with heavy-metal stress.

### 10.3.2 DEHYDRINS AS MARKERS OF PLANT STRESS TOLERANCE

A positive effect of dehydrin gene expression or dehydrin protein accumulation on plant stress tolerance has been reported not only by studies using transgenesis, but also by several other studies which compared varieties or cultivars of economically important plants which differ in their level of stress tolerance. Based on these studies, it is becoming evident recently that dehydrins can be used as indirect indicators of plant stress tolerance (about direct and indirect methods of determination of plant stress tolerance, see e.g., Prášil et al., 2007).

Plant tolerance to the effects of a certain stress factor can be associated with allelic variation in dehydrin sequence, which can result in accumulation or absence of a dehydrin protein in a certain plant tissue or organ. Ismail et al. (1999b) studied chilling tolerance during the process of seedling emergence in an extremely chilling-sensitive tropical legume crop *Vigna unguiculata* and they described a presence of DHN1 protein (Y<sub>2</sub>K-type dehydrin of 35 kDa) in seeds of a chilling-tolerant line 1393-2-11, which correlated positively with seedling emergence at 14°C. In contrast, the DHN1 protein was absent in the seeds of a genetically related, but chilling-sensitive line 1393-2-1.

However, the differences in plant stress tolerance are much more often determined by quantitative differences in dehydrin gene expression or dehydrin protein accumulation. It has repeatedly been proven that the rate of dehydrin transcript or protein accumulation positively correlates with the level of plant stress tolerance. In studies dealing with drought stress, Pelah et al. (1997) found a correlation between drought tolerance and accumulation of dehydrin proteins in *Populus popularis*. Park et al. (2006) have found a correlation between *Dhn3* and *Dhn4* transcript accumulation and several characteristics associated with drought tolerance (relative water content RWC, Drought yield index) in a set of Korean barley cultivars. Similarly, Labhili et al. (1995) found a correlation between the level of dehydrin transcript accumulation and drought tolerance in two differently tolerant cultivars of durum wheat (*T. turgidum* ssp. *durum*). Cellier et al. (1998) have compared two lines of sunflower (*Helianthus annuus*) differing in their drought tolerance and found differences in their leaf water potential under the same gravimetric soil water content. When both lines were compared, the tolerant line had a higher leaf water potential under the same gravimetric soil water content and exhibited also a higher level of expression of two dehydrin genes, *HaDhn1* and *HaDhn2*, not only under the same gravimetric soil water content, but also when the plants with the same leaf water potential were compared. Tolerant line also exhibited higher level of *HaDhn2* gene expression after application of exogenous ABA. Analogously, Tabaei-Aghdai et al. (2000) compared dehydrin protein accumulation in drought-tolerant *Agropyron desertorum* and in a less tolerant *Lophopyrum elongatum* under drought stress (6 days without watering) and detected much higher levels of dehydrin polypeptides in the drought-tolerant *A. desertorum* than in *L. elongatum*.

Brini et al. (2007a) studied DHN-5 accumulation in two cultivars of Tunisian durum wheat (*Triticum turgidum* ssp. *durum*) with different level of drought tolerance. They found differences not only in accumulation of DHN-5, but also in the pattern of DHN-5 phosphorylation. The tolerant cultivar showed a high level of DHN-5 phosphorylation while a sensitive cultivar nearly lacked phosphorylated forms of DHN-5. So it can be postulated that different patterns of dehydrin posttranslational modifications, namely, phosphorylation may underlie the differences in cultivar tolerance to stress.

Quantitative differences in dehydrin gene expression and dehydrin protein accumulation with respect to the low-temperature stress (cold and frost) have been studied especially in economically important cereals from tribe *Triticeae*, which are grown in temperate climates. In bread wheat (*T. aestivum*), Houde et al. (1992b) have already described a correlation between accumulation of dehydrin proteins from the WCS120 family and the level of plant-acquired frost tolerance. At the beginning of these studies, only the differences in dehydrin expression between cultivars (lines) with contrasting levels of acquired frost tolerance (i.e., spring cultivars versus winter ones) were studied (e.g., Zhu et al., 2000). However, Vítámvás et al. (2007) have shown that two winter wheat cultivars with a different level of acquired frost tolerance (Mironovskaya 808 and Bezostaya 1) can be distinguished according to the level of accumulation of WCS120 proteins after a 3 week cold treatment (2°C). Kosová et al. (2008) studied accumulation of cold-inducible barley orthologue of the WCS120 protein, DHN5, and found a correlation between DHN5 accumulation and the level of acquired frost tolerance in a set of 21 barley cultivars of different geographical origin and growth habit (facultative, spring, winter) after a 3 week cold treatment. However, Kosová et al. (2010) have shown that the correlation between DHN5 accumulation and acquired frost tolerance or winter survival rate can be obtained only in those barley plants that are still in vegetative phase of their development.

Stress-tolerant and stress-sensitive related plant species or cultivars belonging to one plant species can be distinguished according to level of dehydrin expression not only under stress conditions,

but also under non-stress (or mild stress) growth conditions or in the early phases of stress treatment. This observation was reported by Xiao and Nassuth (2006) on dehydrin transcript *DHN-1* in leaves and buds of two grapevine species *Vitis vinifera* and *Vitis riparia*, which differ in their frost tolerance. The tolerant *Vitis riparia* revealed higher level of *DHN1* under control conditions and also an earlier increase in *DHN1* level under stress conditions than the sensitive *Vitis vinifera*. In *Triticeae*, it has also been shown by several authors that cultivars of wheat or barley with different levels of frost tolerance can be distinguished according to dehydrin (or other *Cor* gene) expression not only at cold temperatures typical for cold acclimation process (5°C–2°C), but also at mild cold temperatures (17°C–9°C). In the first studies published by Crosatti et al. (1995, 1996), spring versus winter cultivars of barley have been distinguished according to the level of expression of chloroplast-located *Cor14b* gene (a *Lea-3* gene). Later, Vágújfalvi et al. (2000) have distinguished highly frost-tolerant winter wheats Albidum and Uljanovka from the less tolerant winter wheat Cheyenne according to *Cor14b* gene expression using the plants cultivated at 18/13°C (day/night) regimen. Holková et al. (2009) quantified the expression of *Wcs120* gene in four winter wheat genotypes by real-time PCR and they were able to distinguish the genotypes with different frost tolerance at 17°C at transcript level. Vítámvás et al. (2010) used dehydrins from the *Wcs120* gene family, and they were able to distinguish 20 cultivars of different frost-tolerant winter wheats grown at 17°C or 9°C at WCS120 protein level. Moreover, the level of accumulation of WCS120 proteins corresponded well with the level of plant winter survival. Thus, it seems possible to use the level of WCS120 accumulation in wheat plants grown under mild cold temperatures (17°C–9°C) as a means for estimation of plant winter survival. These results could enhance the prescreening procedures in the breeding programmes aimed at the improvement of wheat frost tolerance (or winter survival) immensely since the plants can be grown under relatively high temperatures, thus relatively large amounts of plant material can be obtained much faster when compared with plant growth under cold.

## 10.4 CONCLUDING REMARKS

With increasing data from diverse research fields, dehydrins appear to be an amazingly versatile group of LEA proteins presumably due to their intrinsically unstructured character. They exhibit myriads of functions (e.g., chaperone, cryoprotective, antifreeze, radical-scavenging, ion-binding functions) in plant reactions on various stress factors, including drought, high-salinity stress, low-temperature stress, heavy-metal stress, and also some biotic stresses such as wounding. Several studies carried out on both normal (non-transgenic) and transgenic plants have reported a positive effect of dehydrin transcript or protein (expression) accumulation on plant tolerance to various stress factors. Future research studies will surely bring new insights into the functions of these fascinating proteins and we can hope that these studies will significantly contribute to our better understanding of the roles which these stunning proteins play in the conundrum of plant-stress response mechanisms.

## ACKNOWLEDGMENTS

The authors thank the editor, Professor M. Pessarakli, for helpful comments on the manuscript. This work was supported by grants from Czech Science Foundation GA CR 522/08/1290 and Ministry of Agriculture MZe 0002700604.

## APPENDIX 10.A: LIST OF SEQUENCED DEHYDRINS

The list of sequenced dehydrin proteins summarizes basic data from NCBI database (<http://www.ncbi.nlm.nih.gov/>) available in July, 2009. The individual plant species are ordered according to their scientific Latin names. Basic protein characteristics including dehydrin structural subgroup

according to the presence of S-, K-, and Y-segments, number of amino acids (aa), protein isoelectric point (pI), and molecular weight (MW) in kilodaltons (kDa) are given. The references which are already given above in the reference list are not repeated in the appendix.

***Aegilops umbellulata*** (Zhuk.) Bowden

*Dhn1* (AM180925.1) (CAJ56055.1) gi 121489505—YSK<sub>2</sub>—150 aa—pI 9.36; MW 15.16 kDa (Rampino et al., 2006).

*Dhn2* (AM180926.1) (CAJ56056.1) gi 121489507—YSK—78 aa—pI 9.16; MW 7.83 kDa (Rampino et al., 2006).

*Dhn3* (AM180927.1) (CAJ56057.1) gi 121489508—YSK<sub>2</sub>—139 aa—pI 8.83; MW 14.35 kDa (Rampino et al., 2006).

*Dhn4* (AM180928.1) (CAJ56058.1) gi 121489511—Kn—96 aa—pI 6.83; MW 9.95 kDa (Rampino et al., 2006).

11.1 FREEZING PROCESS AT LOW TEMPERATURES

It is possible to measure changes in the properties of water in living systems that correlate with physiological functions. Changes in dynamic properties of water at different hydration levels indicate the existence of different fractions of water, which may vary in structure and property and presumably play different biological roles (Sun, 2002). Studies have identified the existence of at least four or five fractions of water, presumably relating to different interactions between water and cellular constituents (Pissis et al., 1996; Ratkovic, 1987; Sun, 2000; Vertucci, 1990).

One species of larch (*Laryx dahurica*), for example, survives in the most northerly forests of Siberia, where temperatures commonly reach  $-65^{\circ}\text{C}$  to  $-70^{\circ}\text{C}$ . Nonacclimated seedlings of winter rye (*Secale cereale*), for example do not survive temperatures lower than  $-4^{\circ}\text{C}$  or  $-5^{\circ}\text{C}$ . However, when acclimated, seedlings survive temperatures as low as  $-28^{\circ}\text{C}$  to  $-30^{\circ}\text{C}$ . Both of these examples from the plant kingdom have different mechanisms that allow them to survive such low temperatures (Figure 11.1).

How do plants freeze? Apart of the problem in trying to solve how plants freeze has been the difficulty in determining where freezing in a plant is initiated and how the freezing proceeds propagation throughout the plant. Several questions still remain unanswered: Can plants supercool without extrinsic nucleators? How many nucleation events are needed for a whole plant to freeze? Do barriers exist within plants that influence the rates or ways of ice propagation? How do cold acclimation, antifreeze proteins, anti-nucleators, and elevated  $\text{CO}_2$  affect ice nucleation? And what determines the natural patterns of frost injury present in a field after a freezing event (Wisniewski et al., 2009)? Plants can use both tolerance and avoidance strategies for surviving frost (Sakai and Larcher, 1987; Wisniewski et al., 2009).

The growth of extracellular ice is the most common freezing pattern in plants, which, for example, occurs in the leaves of most plants and in the bark of woody species. Most of this ice grows at the expense of water drawn from within the non-frozen cells. By freezing extracellularly, the cells avoid freezing, but at the expense of suffering partial or extensive dehydration. Plants are not able to tolerate severe extracellular dehydration. Dehydration to the certain level can cause lethal stress (Table 11.1).

The temperature at which ice melts ( $T_m$ ) is well determinable in contrary to the freezing temperature ( $T_f$ ). It is a common knowledge that  $T_m$  and  $T_f$  of pure water is  $0^{\circ}\text{C}$ . Pure water has the ability

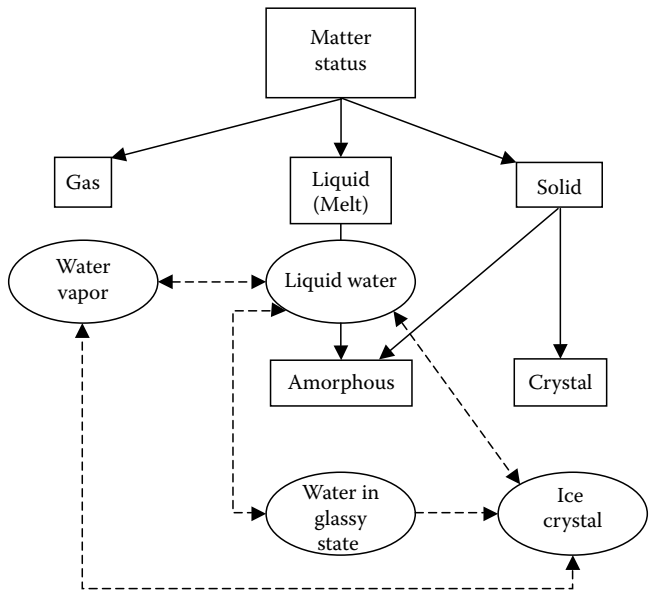

FIGURE 11.1 Status of matter with examples for water.

**TABLE 11.1**  
**Temperature Boundary Marks with Water Physiological Stress Meaning**

| Temperature [°C] | Water/Ice/Glass Transition   | Examples in Plants                              |
|------------------|------------------------------|-------------------------------------------------|
| 0                | Pure water freezing          | Rain drops, dew, on the surface of plants       |
| 0~–38            | Supercooling                 | Trees buds                                      |
| 0~–38            | Heterogeneous ice nucleation | Plant-intrinsic ice nuclei                      |
| ~–38             | Homogeneous ice nucleation   | Limit for supercooling plants                   |
| ~–80             | Ice forms transfer           | Lowest temperature on the Earth                 |
| –135             | Water glass transition       | Cryopreservation in liquid nitrogen vapor phase |
| –196             | Liquid nitrogen              | Cryopreservation in liquid nitrogen             |

to supercool to temperatures as low as  $-40^{\circ}\text{C}$  (Rajashekar and Burke, 1996). Pure water freezes at much warmer, subzero temperatures due to the presence of heterogeneous nucleators that induce ice crystal formation (Franks, 1985) (Figure 11.2).

Freezing is precisely defined as a *first-order phase transition* which involves the crystallization of liquid water. First-order transitions have a latent heat of the transition, they occur at a well-defined transition temperature, and the heat capacity shows discontinuity at the transition temperature. If this water crystallizes from an aqueous solution, then the process of freezing is accompanied by a gradual increase in the concentration of all soluble components in the residual liquid phase. The freeze concentration of an intracellular solution can have dangerous influence on the viability of cells. When the extracellular freezing is involved, the injury is due to the concentration effect. When a plant at the low temperature is accompanied by freezing, damage arises mainly from factors such as changes in ionic activities, reduction in diffusion rates, and a disruption of the energetic balance which is responsible for the maintenance of biologically significant structures—membranes, enzymes, and other macromolecular complexes—and differential changes in the rates of coupled reactions.

**FIGURE 11.2** Water molecules' arrangement in the three states; water molecules in ice crystal are ordered in a regular lattice; water molecules in glass are disordered but are rigidly bound; water molecules in liquid are disordered and are not rigidly bound but they form clusters of molecules.

The melting of a solution is determined by the concentration and types of substances dissolved in the solution. A simple equation describes the relationship between the osmotic potential ( $\Psi_s$  [osmol]) of a solution in equilibrium with ice at subzero temperature ( $T$  [°C]).

$$\Psi_s = \frac{T}{1.86} \quad (11.1)$$

*Freezing point depression* describes the phenomenon that the freezing point of a liquid (a solvent) is depressed when another compound is added. A solution has a lower freezing point than that of a pure solvent. In plants the solutes are concentrated by removing the excess of pure solvent, water. At the freezing point (Beurroies et al., 2004), the solid phase and the liquid phase have the same chemical potential, meaning that they are energetically equivalent. Often during freezing, a solute only dissolves in the liquid water and not in the ice. This means that when such a solute is added, the chemical potential in the liquid phase is decreased by water dilution, but the chemical potential of the water in the solid phase, ice, is not affected.

The chemical potential of a solution is temperature dependent. At some temperatures, either in the solid or in the liquid phase, it has a lower chemical potential and is more energetically favorable than the other phase. This means in turn that the equilibrium between the ice and liquid phase is established at lower temperature for a solution than for a pure liquid; the freezing point is depressed.

The freezing/melting point depression,  $\Delta T_m$ , is defined as

$$\Delta T_m = T_{m(\text{water})} - T_{m(\text{solution})} \quad (11.2)$$

The difference between the freezing points of the pure solvent and the solution is expressed by following equation

$$\Delta T_m = K_m m_B \quad (11.3)$$

where  $K_m$  is cryoscopic constant, which is dependent on the properties of the solvent,  $m_B$  is the molality of the solution, calculated by taking dissociation into account since the freezing point depression is a colligative property, dependent on the number of particles in the solution. This is most easily done by using the van't Hoff factor  $i$  as  $m_B = m_{\text{solute}} i$ . The factor  $i$  accounts for the number of individual particles formed in solution, where  $i$  is, for example, equal to 1 for sugar in water and 2 for sodium chloride in water. So the cryoscopic constant can be calculated as follows (Workmaster et al., 1999)

$$K_m = \frac{R \Delta T_m^2 M}{\Delta H_m} \quad (11.4)$$

where

$R$  is the gas constant

$\Delta T_m$  is the freezing/melting point of the pure solvent (in Kelvin)

$M$  is the molar mass of the solvent

$\Delta H_m$  is the enthalpy of fusion per mole of the solvent

This formula is valid for diluted solution and for ideal solutions.

At high concentrations, Equation 11.2 is less precise due to the approximations used in its derivation and in any non-ideality of the solution. If solute is soluble in solid solvent, one of the key

assumptions used in deriving the formula is not true. In this case the effect of the solute on the freezing point must be determined from the phase diagram of the mixture.

The freezing point of pure water is 0°C. The solutes in plant cells depress the freezing point of water below 0°C. The extent to which the freezing point is depressed below 0°C is proportional to the concentration of dissolved solute particles (see Equations 11.2 and 11.3); a 1 molal solution of an ideal non-ionized solute freezes at -1.86°C and has an osmotic potential of -2.27 MPa. Based on this relationship, the freezing point depression of any unknown solution can be calculated from the osmotic potential, as comes from Equation 11.1

$$\Delta T_m = \frac{\Psi_s}{1.221} \quad (11.5)$$

where

$\Psi_s$  is osmotic potential of solution (MPa)

1.221 is constant (MPa deg<sup>-1</sup>)

Since this equation is valid for solutions at 0°C (273 K), we must correct the equation to room temperature by multiplying the equation by the ratio of the absolute temperatures (room temperature in K/273 K)

$$\Delta T_m = \frac{\Psi_s}{1.221 T_a / 273} \quad (11.6)$$

where  $T_a$  is room temperature in K. Freezing point depression is generally produced by concentration of solutes in tissue.

With freezing, the extracellular solution becomes more concentrated and water therefore leaves the cell until the gradient in chemical potential is equilibrated, establishing osmotic equilibrium across the plasma membrane. This new equilibrium results from the concentration of the intracellular solutes. The equilibrium cell volume  $V$  is a function of the extracellular solute concentration and has traditionally been expressed by the Boyle–van't Hoff equation

$$V = \Psi_s^o (V^o - b) \left( \frac{1}{\Psi_s} \right) + b \quad (11.7)$$

where

$\Psi_s$  is the osmolality of the extracellular solution

$b$  is the osmotically inactive volume of the cell

$V^o$  and  $\Psi_s^o$  are the cell volume and the extracellular osmolality, respectively, for the isotonic condition

Note that the Boyle–van't Hoff equation is derived by assuming that the cell contents form a thermodynamically ideal, dilute solution. The Boyle–van't Hoff plot can show the relative cell volume as a function of inverse osmolality. The extrapolation of a straight line to infinite osmolality has been used to estimate the osmotically inactive fraction of the cell volume (Burke et al., 1976; Gusta et al., 1975). The rate of movement of water across a membrane is limited by the permeability properties of the membrane. The rate at which the cell loses water or input water after thawing is a function of the magnitude of the water vapor gradient and the

permeability of the plasma membrane (the area of the membrane and its conductivity to water) and is given by the following relation

$$\frac{dV_w}{dt} = L_p A R T (\Psi_i - \Psi_e) \quad (11.8)$$

where

- $V_w$  is the water volume of the cell
- $t$  is time
- $L_p$  is the hydraulic conductivity
- $A$  is the membrane surface area
- $R$  is the gas constant
- $T$  is the absolute temperature
- $\Psi_i$  is the intracellular water potential
- $\Psi_e$  is the extracellular water potential

For vapor phase see Equation 11.12.

In practical sense the osmotic potential of cell samples can appear after the tissue freezes to the temperature at which the cells ruptured. The osmotic potential after freezing and thawing cannot reflect the actual situation during freezing. The intact tissue volume can mix with the apoplastic water volume and, after thawing, the osmotic potential can be much higher because of the dilution effect of extracellular water with intracellular sap.

The effect of osmotic potential on the freezing point depression also holds for non-ideal solutions. However, the freezing point depression is non-linear with concentration changes during dehydration. Water potential (MPa at 0°C) can be derived by the following empirical equation (Crafts et al., 1949; Wisniewski et al., 2009):

$$\Psi_s = -1.206 \Delta T_m + 0.0021 \Delta T_m^2 \quad (11.9)$$

During lowering the temperature, the sample is usually supercooled a few degrees below its freezing point. After the induction of crystallization, as the heat of fusion is released, the sample temperature rises to its freezing point, at its temperature equilibrium. Similarly, the temperature at which ice crystals start to melt was taken as the equilibrium thawing temperature.

### 11.1.1 SUPERCOOLING

Supercooling occurs when solution freezes at temperature lower than at the freezing point. Supercooling is important to the surviving plants' low temperature stress. The ice nuclei have cluster form as like ice lattice in shape and size critical for certain temperature (Šesták and Zámečník, 2007). During heterogenic ice nucleation, the critical size and shape are formed from external impurity with the ability to start nucleation. In the nature the most common external ice nucleators come from frozen dews, snowflakes, small ice crystals, or epidemic ice-nucleating bacteria on plants. When water is cooled below 0°C, and in the absence of ice nuclei it can be supercooled down to approximately -40°C. As an example, pure water droplets of about 10 μm in diameter supercooled to -38.1°C, provided no heterogeneous nucleators were presented by Rasmussen and Mackenzie (1972). The spontaneous nucleation temperature is influenced by the concentration of solutes reflecting in freezing point depression, as shown in the following equation:

$$T_h = -(38.1 + 1.86 \Delta T_m) \quad (11.10)$$

where

- $\Delta T_m$  is the freezing point depression for the solution (in K)
- $T_h$  is the homogeneous nucleation temperature (in °C)

The proportionality constant has a theoretical value 1.86; for most low molecular substances the value is 2 and for few polymers this constant lies between 4 and 6 (Franks, 1985).

So solution in plant cells may be supercooled to a lower temperature than supercooled pure water, usually from  $-41^{\circ}\text{C}$  to  $-47^{\circ}\text{C}$ , because cell solutes depress the homogenous nucleation temperature. In small holes in plants the water can be supercooled to below  $-40^{\circ}\text{C}$ . In laboratory experiments with the distilled water, supercooling cannot reach temperature below  $-20^{\circ}\text{C}$ . The supercooling of the cell contents would avoid ice crystal formation. However, if the supercooling limit of cells is exceeded, then intracellular freezing occurs more often, and it is generally accepted that intracellular ice formation is lethal for plants (Guy, 1990). Most tropical plants are unable to protect themselves against freezing, but most species of temperate plants can acclimate to cold, so the ice forms only outside the cells as the temperature drops.

Deep supercooling, from about  $-15^{\circ}\text{C}$  down to a limit of about  $-40^{\circ}\text{C}$ , occurs in many temperate woody plants such as apple and maple tree. Deep supercooling is the only way for woody plants to withstand severe winters. Deep supercooling is limited to only certain organs or tissues. For example, in apple tree the cells of the xylem parenchymal cells deep supercool. The highest ice nucleation activity (INA) was found in apple twig bark  $-3.9^{\circ}\text{C}$  and brachyblast  $-4.9^{\circ}\text{C}$ . The average INA was not exceeded in xylem sap  $-7.4^{\circ}\text{C}$  and in extract from stem  $-6.7^{\circ}\text{C}$  (Bilavcik et al., 1997) (Figure 11.3).

Maple, deep supercool but the bark freezes extracellularly (Ashworth et al., 1988). In forsythia and maple, cells in flower bud organs supercool but the bud scales and nearby stems, again, freeze extracellularly (Ashworth, 1990; Ishikawa et al., 1997).

More unusual phenomena may occur in the extreme freezing tolerance; below the  $-40^{\circ}\text{C}$  limit of water drops to deep supercool. In the xylem parenchyma of the red osier dogwood, ice forms between the cell wall and the plasma membrane outside the protoplast, without damaging it (Ashworth, 1996).

The deep supercooling of the xylem is found in many temperate deciduous trees. The xylem ray parenchyma cells are generally believed to deep supercool and as such remain viable, whereas the freezing of these cells is lethal. However, with the nuclear magnetic resonance (NMR) images resolution investigation of full moon maple, it is not possible to confirm whether only the xylem ray

**FIGURE 11.3** An average ice nucleation activity (potential supercooling temperature) of an apple blooming twig parts. Twig parts were detached and ice nucleation were measured by thermobattery with thermocouple in each drop in connection as differential thermal analysis. (From Bilavčik et al., 1997.)

parenchyma supercool as the images appear as the entire xylem remained unfrozen. In contrast, in full moon maple flower buds, deep supercooling was detected between the mature pith and not in the xylem (Ishikawa et al., 2009).

### 11.1.2 ICE NUCLEATION

The critical size for a homogenous nucleus to begin ice crystal growth is 45,000 water molecules at  $-5^{\circ}\text{C}$ , 650 water molecules at  $-20^{\circ}\text{C}$ , and only 70 water molecules at  $-40^{\circ}\text{C}$  (Vali, 1995). Below the critical size a spontaneous dissolution of the ice nuclei occur due to solubility. Thus, the temperature of homogenous nucleation is a function of sample volume and of time. But the function is an exponential one, with nucleation decreasing so rapidly above  $-40^{\circ}\text{C}$  that it is rarely seen more than a few degrees above  $-40^{\circ}\text{C}$  (Zachariassen and Kristiansen, 2000). The probability of a volume  $V$  of pure water freezing in time  $\Delta t$  due to homologous nucleation is  $J(T)$  times  $V$  times  $\Delta t$ .  $J(T)$  is nucleation rate at temperature  $T$ , determined by the empirically derived equation

$$J(T) = 6.8 \times 10^{-50} e^{-3.9T} \quad (11.11)$$

for  $J(T)$  in  $\text{m}^3 \text{s}^{-1}$  and  $T$  in  $^{\circ}\text{C}$  (Vali, 1995). The  $e^{-3.9T}$  factor means that the probability of nucleation increases by about 50 for each drop of  $1^{\circ}\text{C}$  or by over 6 million for a  $4^{\circ}\text{C}$  temperature drop (Ashworth and Wisniewski, 1991). Although volume and time are linear components in the probability, the exponential temperature component means that the probability rapidly goes from zero to one in the temperature range between  $-38^{\circ}\text{C}$  and  $-42^{\circ}\text{C}$  (being very close to  $-40^{\circ}\text{C}$  for all practical purposes).

The initial formation of extracellular ice in plants is under the control of ice nucleators (Brush et al., 1994) and antifreeze proteins (Hon et al., 1994). Extracellular ice is relatively benign, but acts as a nucleation site for water vapor drawn out of the cell, thereby desiccating the cell. As a consequence, cell volume decreases, but the cell wall remains appressed to the plasma membrane, and ice crystals generally forms between cell wall junctions. It confirms that in this stable state that most cold-stressed tissues overwinter at subzero temperatures. A hydrophilic protein with the potential of conferring desiccation tolerance was found in the vascular transition zone of the wheat crown, which is critical tissue for winter survival (Houde et al., 1995). However, ice-driven desiccation can continue to the point of nonreversible cellular damage. The formation of ice within plants and mechanisms of freezing tolerance have been discussed in review (Gusta et al., 2009a).

The INA of bacteria has been well characterized (Lindow, 1995) and the protein, and corresponding gene, have been isolated and identified (Lindow et al., 1989). In contrast, while INA of plant origin has been commonly observed, especially in woody plants (Ashworth and Kieft, 1995; Lindow, 1995), plant ice nucleation active compounds have not been identified and remain ambiguous, as does an understanding of their origin, development, distribution, turnover, and the role in adaptation to freezing temperatures. The composition of plant ice nucleation active substances is referred in wide scale, from a soluble (Embuscado et al., 1996; Krog et al., 1979) or structural (Chalkerscott, 1992) polysaccharide (Gross et al., 1988) to a protein (Constantinidou and Menkissoglu, 1992) or to a complex molecule such as a phospholipid. The temperature at which extrinsic nucleation occurs in plants appears to be an adaptive process requiring *de novo* synthesis, as it is influenced by cold acclimation (Ball et al., 2002; Beerling et al., 2001; Ishikawa et al., 2009; Lutze et al., 1998).

Although ice nucleation is frequent in woody plants, it also occurs in some herbaceous plants such as *Veronica* (Kaku, 1973) and is often a constitutive feature, present in plants during the whole year. The intrinsic nucleators extracted from plants result in a loss of ice nucleation activity, indicating that a structural component may be essential for them to improve their ice nucleation ability (Griffith and Antikainen, 1996). As a rule, inoculation with ice crystals is a prerequisite for the initiation of extracellular freezing of a cell that is not already in a considerable state of supercooling.

Subzero temperatures experienced by plants in field conditions do not necessarily accompany the occurrence of ice nucleation. Even in the absence of extrinsic ice nucleators, the tissues of cold-hardy plants that undergo extracellular freezing readily freeze at high subzero temperatures and avoid excessive supercooling of the tissues. *Lobelia* species, for example, appear to positively control the initiation of freezing by producing ice-nucleating substances. By the freezing of water involving latent heat of freezing, it prevents too great a drop in temperature in the hollow inflorescence axes of *Lobelia telekii* (Krog et al., 1979).

Why the scale tissues of Japanese azalea freeze spontaneously during cooling to  $-7^{\circ}\text{C}$  was determined. The outer and inner bud scales ( $-5.9^{\circ}\text{C}$  and  $-6.8^{\circ}\text{C}$ , respectively) which freeze first and act as ice sources had the highest ice nucleating activity, while the florets which remain supercooled lacked effective INA ( $-13^{\circ}\text{C}$  to  $-16^{\circ}\text{C}$ ). In the twigs, the bark tissues that undergo extracellular freezing had a high INA of  $-6.3^{\circ}\text{C}$ . The same findings with higher nucleation activity in bark of apple twigs at  $-3.9^{\circ}\text{C}$  and at  $-4.9^{\circ}\text{C}$  in brachyblast were observed (Bilavcik and Zámečník, 1996).

In contrary xylem and pith tissues of Japanese azalea which undergo deep supercooling had low INA ( $-12.8^{\circ}\text{C}$  and  $-12.4^{\circ}\text{C}$ , respectively) (Ishikawa et al., 2009). The INA of each tissue closely corresponded with its freezing behavior.

These INA values in scale tissues of Japanese azalea were affected only slightly by a fourfold increase in the tissue amount and also by an increase in the incubation time at subzero temperatures. The high INA in the outer scales and bark tissues was unaffected by the homogenization of the tissues into fine powders and subsequent extensive washings (Ishikawa et al., 2009). The substances responsible for the INA in each tissue have different sensitivities to heat treatment: the high INA in the bud scale tissues was unaffected by autoclaving ( $121^{\circ}\text{C}$  for 15 min), while the high INA in the bark tissues was sensitive to autoclaving (decreased from  $-11^{\circ}\text{C}$  to  $-12^{\circ}\text{C}$ ). The subcellular fractionation of the ice nucleation activities in the bark by differential centrifugation revealed that the ice nucleation activities were associated with the cell-wall-rich fraction (Ishikawa et al., 2009). These results imply that these ice nucleation activities do not arise from macrostructures such as the presence of trichomes or the outer scales or bark situated in the outermost part of the buds or stems, but from substances tightly bound to the cell walls (Ishikawa et al., 2009; Muryoi et al., 2004). This suggests that these ice nucleation activities are specific to the tissues and their age (Luis et al., 2007).

Nevertheless, several intrinsic nucleators have been partly characterized. Mucilage and carbohydrates, respectively, appear to be the nucleators in *Opuntia* and in giant high-altitude African species of *Lobelia* (Goldstein and Nobel, 1991). Interestingly, cell wall arabinoxylans may have an opposite antifreeze effect in rye and barley crowns and seeds (Kindel et al., 1989; Olien and Smith, 1977). The nucleator in peach and apple trees nucleator appears neither proteinaceous nor lipidic in composition (Ashworth et al., 1985). In contrast, nucleators from rye are proteinaceous, though they also included phospholipids and carbohydrate components (Vali, 1995). Thus, all plant-intrinsic ice nucleators are not of one kind.

### 11.1.3 SEASONAL INA DEPENDING

The flower bud scales of Japanese azalea showed seasonal changes in INA. The outer and inner scales of late August flower buds (just completed morphological development) had low INA; from there on INA increased and attained the maximum activity in late October or early November at the time of the first frost (Ishikawa et al., 2009). In winter, INA was maintained at high level. Interestingly, the flower bud scales of tropical *Rhododendron* species had very low INA irrespective of the season (Ishikawa et al., 2009). These authors surveyed the INA of various tissues of nearly 500 species, ranging from tropical to boreal plants and found that cold-hardy plants from temperate to boreal regions in general showed higher INA in some tissues compared with tropical plants. These results imply that when cold-hardy plants cold acclimate, they regulate freezing by producing intrinsic ice nucleators in tissues that undergo extracellular freezing or tissues that act as an ice sink in extraorgan freezing. It appears that tropical plants (sensitive to freezing) lack such

intrinsic ice nucleators and supercool extensively (lower than  $-7^{\circ}\text{C}$ ). When freezing does occur, it is lethal presumably due to intracellular freezing. The isolation and identification of such intrinsic ice-nucleating substances has not to our knowledge been successful. The level of supercooling goes down to  $-41^{\circ}\text{C}$  (Burke and Stushnoff, 1976) as the solid, denser form of water is the hexagonal ice having the structure that is uncanonical with respect to the pentagonal-like symmetry of a solidifying liquid that contains a high number of incommensurable nuclei of icosahedra and dodecahedra.

#### 11.1.4 ANTI-ICE-NUCLEATING ACTIVITIES

Anti-ice-nucleating activities can occur in three ways. (1) The different tissues have their specific INA, with or without specific ice-blockers. (2) Plants have barriers between organs and tissues to avoid spreading the ice nucleation (ice front) to other organs or to slow down spreading the ice front. (3) Third possibility is to produce specific ice-blocker which can inhibit INA of either plant intrinsic or extrinsic origin. The rate of ice propagation in veins was significantly higher at lower temperatures and reached to  $24\text{ cm s}^{-1}$  (Hacker and Neuner, 2008).

##### 11.1.4.1 Specific Ice Nucleation Activity

Since deep supercooled tissues such as florets and xylem ray parenchyma are too small, it is difficult to obtain a sufficient amount of these tissues (without contamination from other tissues) for biochemical analyses. To overcome this problem, Larcher et al. (1991) selected *Trachycarpus fortunei*, which is probably the most cold-hardy palm species and employs deep supercooling as the mechanism of cold hardiness in most of its leaf tissues. The leaf tissues of this species tolerated  $-14^{\circ}\text{C}$  without any injury. NMR micro-imaging with a resolution of  $31\text{ }\mu\text{m}$  successfully visualized non-invasively, the freezing behavior of *Trachycarpus* leaves. Water in the vascular bundles and epidermis froze at  $-10^{\circ}\text{C}$ , which corresponds to the higher temperature exotherm (HTE); however, the mesophyll cells remained deep supercooled to  $-14^{\circ}\text{C}$ . The cells on the adaxial side froze first, mostly between  $-16^{\circ}\text{C}$  and  $-19^{\circ}\text{C}$ , followed by freezing of cells on the abaxial side ( $-19^{\circ}\text{C}$  and  $-21^{\circ}\text{C}$ ). The hypodermis and vascular sclerenchyma remained deep supercooled to  $-22^{\circ}\text{C}$  or lower (Ishikawa et al., 2009). This implies that *Trachycarpus* leaves may have mechanisms to remain supercooled in a stable manner and/or to avoid the ice nucleation. At least several compounds are involved in the anti-nucleating activity but it still remains unknown whether they also confer supercooling stabilizing activity or not (Ishikawa et al., 2009; Wisniewski et al., 2009).

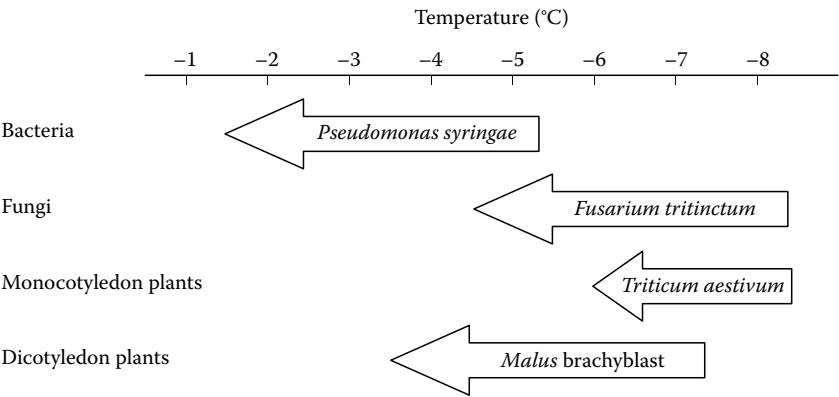

##### 11.1.4.2 Barriers to the External Ice Nuclei

The origin of external ice nuclei can recruit from dust, soil particles, and ice crystals, in case of biological ice nucleation from bacteria and fungi (Zámečník et al., 1991). A comparison of ice nucleation of bacteria cells and fungi spores, depending on their concentration with higher ice nucleation temperature, is shown in Table 11.2.

The presence of stomata, lenticels, and injured small surface trichomes or epidermal cell seems to be the gates for ice nucleation. Often, the growth of surface ice into the plant appears to be much less important than the spread of freezing throughout the plant from intrinsic nucleation events (Pearce, 2001; Wisniewski et al., 1997). New technique, high-resolution infrared (IR) thermography (Fuller et al., 2009; Gusta et al., 2004; Hacker and Neuner, 2007, 2008) has been used for thermal behavior of water during cooling the plants. By this technique, the ice nucleation induction and ice spreading through the plant have been studied more.

*Hydrophobic barriers to ice propagation* were shown clearly on rhododendron. Wisniewski et al. (1997) proved that the cuticle blocks an external ice as ice nuclei from inducing an internal nucleation event. Thick cuticle as a barrier to the ice propagation was also confirmed in cranberry. Wisniewski and Fuller (1999) demonstrated that ice crystals must physically grow through a crack in the cuticle of a non-tolerant plant, i.e. bean leaves (*Phaseolus vulgaris*), of broken epidermal hair, or of a stoma to induce ice nucleation within the leaf and the whole plant. From this it can be

**TABLE 11.2**  
**Example of Highest Nucleation Temperature for Bacterial Strain at Concentration  $10^8$  cfu mL<sup>-1</sup>, Fungi Spores in Concentration of  $10^5$  mL<sup>-1</sup>, Expressed Sap from Winter Wheat Crowns in Cold-Hardened Stage and Apple Brachyblast Collected from Tree in Mid-Winter Time**

*Notes:* Ice nucleation was measured in all samples with the same droplet freezing method by thermobattery in thirty 10  $\mu$ L drops at cooling rate 1°C min<sup>-1</sup>. Water for dilution was double distilled water with average nucleation temperature -18°C (Zámečník unpublished).

concluded that the cuticle acts as a primary barrier to the ice propagation from external sources of ice, probably due to their hydrophobic properties. Coated tomato (Wisniewski et al., 2002b) and potato plants (*Solanum tuberosum*) support this hypothesis. In the case of tomato, leaves coated with hydrophobic particle film have the temperature of ice nucleation 3.5°C lower than non-coated leaves sprayed with ice nucleation active (INA) bacteria (Wisniewski et al., 2002b).

**11.1.4.3 Barriers to Internal Ice Propagation**

Barriers to the spread of ice are common in woody plants, though often the nature or mode of functioning of the barrier is unclear. However, in forsythia and peach the growth of xylem into buds in the spring removes a barrier to ice (Ashworth et al., 1992). In plants there are also simple structures and specific macromolecules that appear to have a specific role in controlling nucleation of freezing or growth of ice (Zámečník, 1996). The supercooling of different plant parts could be important for survival and these barriers to ice propagation disappear due to seasonal pattern (Figure 11.4).

**11.1.4.4 Plant Structure and Its Role in Formation and Propagation of Ice**

It has been commonly observed that the formation of ice within a plant does not occur in a uniform manner but rather at selected sites where ice preferentially accumulates [reviewed by McCully et al. (2004) and Ishikawa et al. (2009)]. The factors associated with the determination of sites of ice formation and accumulation are not clearly understood. The mid-rib of leaves, the base of petioles, areas near vascular bundles, and phloem fibers all have been identified, using IR technology, as common sites for initial nucleation events. Ice nucleation in rape leaves that comes either from mid-vein, small veins, and/or mesophyll between veins (Zámečník, unpublished). Carter et al. (2001) and Fuller et al. (2009) have noted the existence of barriers within a plant that influence the direction and, thus, the rate of ice propagation. In some cases, this may directly affect the resulting pattern of injury that has occurred. It appears that where ice forms, how it propagates, and how it is accommodated are all important factors that affect the ability of a plant to survive freezing and may be as

**FIGURE 11.4** Harmonic mean with standard error of ice propagation rate in the equal distance of root-mesocotyl, mesocotyl-mesocotyl, mesocotyl-crown.

important as the ability to withstand the dehydration stresses associated with ice formation. Gusta et al. (2009b) conducted a detailed analysis of ice formation in the petioles of two frost-tolerant herbaceous plants. It was concluded that these plants have evolved a complicated arrangement of structural strengths and weakness within petiole tissues, which enables them to accommodate large volumes of intercellular ice during freezing events. These findings raised several questions regarding the composition and quality of the cell walls associated with the points of strengths and weakness, and the mechanism of water movement to and from the sites of ice formation.

#### 11.1.4.5 Specific Ice-Blocker

Boreal hardwood species had xylem parenchyma cells that adapt to subfreezing temperatures by deep supercooling. Crude extracts from xylem in all these trees were found to have anti-INA that promoted the supercooling capability of water. The magnitude of the increase in supercooling capability of water droplets in the presence of ice-nucleation bacteria, *Erwinia ananas*, was higher in the range from 0.1°C to 1.7°C on addition of crude xylem extracts than freezing temperature of water droplets on addition of glucose in the same concentration (100 mosmol kg<sup>-1</sup>) (Kasuga et al., 2007).

INA bacteria were also used for the detection of anti-nucleation activity of wheat and triticale seedlings. The ice nucleation activity of INA bacteria of *Pseudomonas syringae*, strain CCM 4073, was depressed by 1.1°C, with expressed sap from hardened winter-hardy wheat and triticale cultivars (Zámečník and Janacek, 1992). Consequently expressed sap from plants contains intrinsic ice nuclei that have no additional effect on ice nucleation of INA bacteria. The expressed sap from nonacclimated seedling of both species has no significant effect on the ice nucleation temperature of INA bacteria as well. Sun (2002) and Wisniewski et al. (2002a) indicated that by somehow blocking the activity of extrinsic nucleating agents, one may allow plant to supercool to a lower temperature and thereby provide some frost protection (Fuller et al., 2003). They used IR thermography to examine freezing in young tomato (Wisniewski et al., 2002b) plants and determine if a hydrophobic barrier on the plant surface prevents the action of extrinsic nucleating agents.

### 11.1.5 FROST DESICCATION/DEHYDRATION

The rate at which the volume of intracellular water changes with temperature was expressed by Mazur (1963) as follows:

$$\frac{dV}{dT} = \frac{kART}{V_i^o} \ln \frac{p_e}{p_i} \quad (11.12)$$

where

$k$  is the permeability constant of the cell  $\mu\text{m}^3$  water per  $\mu\text{m}^2$  cell membrane surface per minute per difference in water vapor pressure (between inside and outside the cell)

$A$  is the cell membrane area

$V_i^o$ , the molar volume of water

$p_i$  and  $p_e$ , the vapor pressures of supercooled water inside and at thermodynamic equilibrium outside the cell, respectively

$R$  is the gas constant

$T$  is the temperature

From this formula, the rate of water loss in extracellularly frozen cells, as the temperature decreases, is mainly determined by three parameters: (1) permeability constant, (2) surface area of the cells, and (3) difference in the vapor pressure between the supercooled water inside and over the ice outside the cells. The rate of diffusion of water to ice outside the cells is limited by the permeability of plasma membrane lipids. Therefore, if the temperature drops rapidly enough, the diffusion to the extraplasma-  
tic ice cannot occur with sufficient speed.

Woody plants tolerating ice crystals in their tissues have three strategies to survive temperatures below zero. The first living strategy is avoiding freezing by supercooling or lowering of melting point of their tissues and organs (Malone and Ashworth, 1991). Supercooling is a known status in many plants and plant tissues; in parenchymatic cells (Ristic and Ashworth, 1994) and in whole organs as generative buds of *Malus* (Bilavcik and Zámečník, 1996).

The second strategy of plants to stay alive after low temperatures thawing is tolerating of extracellular freezing. The survival of such plant cells/tissues is based on their tolerance to excessive dehydration of the protoplast. Some plant tissues survive temperatures even below  $-40^\circ\text{C}$  in the nature, and in the techniques used for preservation of plant genetic material they survive cryo-temperatures as low as  $-196^\circ\text{C}$ . Cell resistance to volume changes during extracellular freezing leads to cell tension during extracellular freezing. As a cold acclimation in leaves of many evergreen broadleaf species, supercooling stem xylem was associated with an increase in cell wall rigidity (Rajashekar and Lafta, 1996). Cold-hardy stem xylem developed cell tension as high as 27 MPa whereas cold-hardened leaves of live oak (*Quercus virginiana*) developed peak cell tension of 16.8 MPa during an extracellular freezing. The cell rigidity affects freeze-induced dehydration and the supercooling behavior of plant tissues. A relationship between bulk modulus and cell dehydration, including the extreme case where supercooling occurs, has been developed.

The third strategy of plants to survive frost is so-called extraorgan freezing (Sakai, 1982). By this type of strategy the whole plant organ such as bud is protected against ice nucleation and spreading, and the external ice formation exposes the bud to frost dehydration (Chalkerscott, 1992). The above-mentioned survival strategies of plant species tolerating ice in their tissues can be combined; for example, the woody plants can exhibit extraorgan freezing in their buds, extracellular freezing in their bark tissues, and supercooling in their parenchymatic cells of xylem rays. The question is what is the state of water in the plant cells subjected to low subzero temperature. The physical rule states that supercooled liquid changes to the glass at the glass-transition temperature ( $T_g$ ). Glassy state found in dormant twig of poplar tree (Hirsh et al., 1985) offers the explanation, in which state water can be found in frozen tissues. Authors suppose that this state occurred thanks to the freezing dehydration of tissues.

### 11.1.6 COLD ACCLIMATION

A common example of how single stress can increase resistance to other stress is how water deficit can increase of a single resistance to low temperatures. There are many other examples described in literature, for example, rye (Siminovitch and Cloutier, 1982) and wheat (Cloutier and Siminovitch, 1982). The short water deficit induces a dehydration and loss of turgor which by itself decreases ice formation after a subsequent low temperature stress (Palta, 1990).

The main handicap to active growth and metabolism at temperatures close to 0°C lies in the slowness of chemical reactions under these conditions, which can be overcome only by a correspondingly higher efficiency of all essential enzymatic mechanisms. This interesting aspect of the problem is largely unexplored.

Freezing damage is in general not a consequence of low temperature per se, but rather the result of cellular dehydration brought about by extracellular ice crystallization. Cellular membranes have been recognized as the primary sites of freezing injury. A *freezing tolerance* is defined as the ability of plants to survive ice formation in extracellular tissues without a significant damage of membranes or other cell components. It is the result of physiological, chemical, and physical consequences.

Furthermore, the exposure to frost after cold acclimation enhances the level of the freezing tolerance and of the gene expression (Pearce et al., 1998), indicating that the dehydrating effect of freezing might have a signaling role. Thus, a water-stress signal can be additional to or integral to the cold signal.

### 11.1.7 ANTIFREEZE PROTEINS

Published reports on Plant Antifreeze Proteins (AFPs) (proteins that bind to ice crystals and affect their morphology, and have the ability to inhibit nucleating compounds, exhibit hysteresis in very low extents unlike those found in fish and insects) and anti-nucleators (compounds that inhibit the activity of nucleating agents but do not exhibit hysteresis) have added to the complexity of our understanding of what induces a plant to freeze (Griffith et al., 2005; Griffith and Yaish, 2004; Ishikawa et al., 2009). There are many other peptides induced by low temperatures that play a crucial role during hardening but these are not connected with ice formation as the AFP. The AFPs are the only ones of the stress proteins about which the binding to ice crystals is well documented and, moreover, they have specific binding to different ice crystal planes. The plant AFP analysis is problematic, because their isolation is difficult due to their low abundance in the apoplast, in contrary to arctic fish (Figure 11.5).

Griffith and coworkers (Hon et al., 1995) first reported that three Pathogenesis-Related (PR) proteins in the apoplast of cold-hardened winter rye have antifreeze activity. Antifreeze activity has been detected in the apoplast and also in triticale leaf and crown (Zámečník and Bieblova, 1994). Later, the antifreeze activity was also found at a polygalacturonase inhibitor homologue in carrot (Worrall et al., 1998; Meyer et al., 1999), a heat-stable protein in perennial ryegrass (Kuiper et al., 2001), a leucine-rich repeat-containing protein in wheat (Tremblay et al., 2005), and a WRKY protein in *Solanum dulcamara* (Huang and Duman, 2002).

The function of these AFPs in the apoplast of herbaceous plants which undergo extracellular freezing is not very clear, since the degree of thermal hysteresis (i.e., actual prevention of initiation of freezing) generated by these proteins is small. It is generally thought that they also inhibit the recrystallization of ice and thus maintain ice crystals in non-injurious small sizes during prolonged exposure to subzero temperatures, which may contribute to winter survival. (Zámečník et al., 2010) Wang et al. (2002) found that carrot AFP lost half of its recrystallization inhibition activity within 10–20 weeks at –80°C storage (Figure 11.6).

The presence of rye antifreeze activity has been shown to improve the freeze survival of non-acclimated ray suspension cells (Pihakaski-Maunsbach et al., 2003) and to influence freezing patterns of rye plants (Griffith et al., 2005). However, extracts from spruce, fir, and hemlock do not contain AFPs (Duman and Olsen, 1993); it might be that AFPs are not a universal component of freezing-tolerant plants (Figures 11.7 and 11.8).

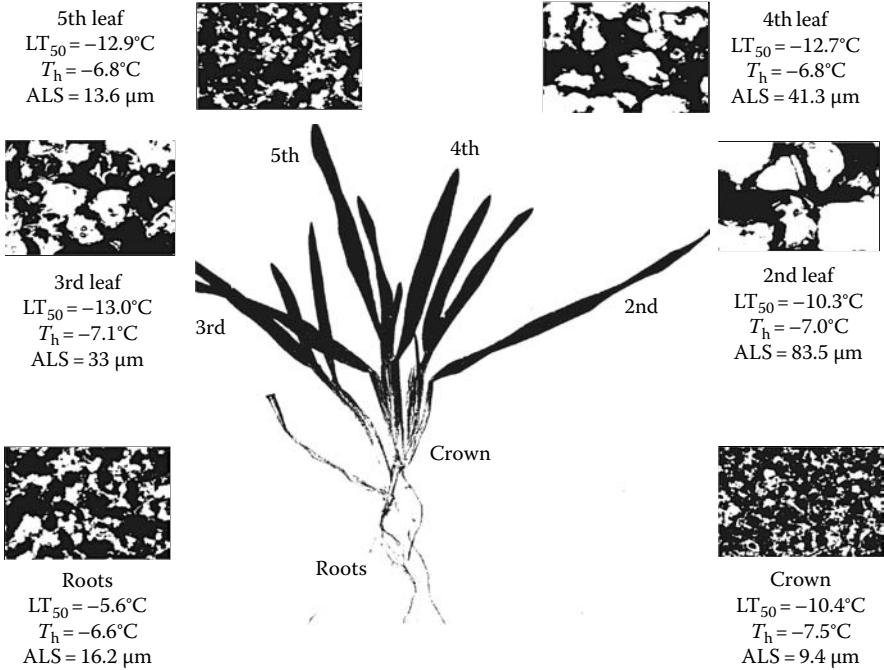

**FIGURE 11.5** Mode of action of antifreeze protein (AFP) binding on ice crystal. The proteins stop ice crystal growth in the  $a_1$ ,  $a_2$ , and  $a_3$  axes. Ice crystal growth is not so influenced in  $c$  axes, resulting in double spicks of ice crystal.

**FIGURE 11.6** Ice nucleation activity was (INA<sup>+</sup>) investigated by freezing droplet assay. Relative frequency of cumulative ice nucleation spectra of thirty 10  $\mu$ L drops. Nucleation event as a heat release of each drop was measured by thermobattery, with thermocouple in each drop in connection as differential thermal analysis. As a source of ice nucleation bacteria, *Pseudomonas syringae* strain CCM4073 in concentration  $10^7$  cfu with high nucleation activity ( $-3.6^\circ\text{C}$  of 50% frozen drops) and antifreeze proteins (AFPs) from extracellular washing of cold-hardened triticale seedling was used. Antifreeze proteins shifted nucleation temperature of bacteria after mixing with AFPs. *Note:* The absolute number of bacterial cells was equal in both samples (Zámečník and Janáček, unpublished).

**FIGURE 11.7** Ice crystals grown from distilled water undergoing recrystallization at  $-8^{\circ}\text{C}$ . (a) Recrystallization inhibition by antifreeze proteins from cold-hardened winter rye (cv. Musketeer) of  $1.18\text{ mg mL}^{-1}$ . (b) Bar is  $100\mu\text{m}$ . *Note:* Both figures are in the same magnification.

**FIGURE 11.8** Heterogeneity of frost resistance (expressed as lethal temperature  $LT_{50}$  after controlled freezing test in different low temperatures). Antifreeze protein activity (expressed as average linear size of crystals). Supercooling ability (measured by thermobattery, temperature was taken when a half of tested samples froze) of different organs of full cold-hardened winter wheat plant (Zámečník, unpublished).

### 11.1.8 WINTER HARDINESS

Tolerance to freezing temperatures is important in agriculture, where the ability to withstand late spring or early autumn frosts may determine the success of further growth and crop yield. In order to fully understand how plants are able to acclimate to low temperatures, it is helpful first to understand how and where freezing occurs in plants and how it causes damage.

The relative importance of stress factors causing winterkill can vary greatly among regions. In Ukraine, an analysis of data from the last 100 years showed that winterkill was caused by low temperatures in 35% of cases, by alternate freezing and thawing in 26% of cases, and by ice encasement in 22% of cases in the years when significant winter damage occurred. Poltarev et al. (1992) stated that the critical factors that affect winter survival in Poland are low temperature, freeze-induced desiccation, and infection by pathogenic fungi. Gusta et al. (1997) reported that the main factors responsible for winterkill in the Great Plains of North America are long periods of cold-induced desiccation, poor acclimation conditions in fall, and unpredictable timing and duration of extremely cold temperatures, whereas the primary cause of winterkill in western Canada is the freeze-induced desiccation. In the Czech Republic, the stability of frost resistance is of the main importance because the weather changed from maritime to continental and during winter all stresses caused by winter factors can occur.

Olien (1967) found that *winterkill* is most likely to occur during low-temperature stress following a midwinter thaw, when the crown tissues have a high moisture content. However, the basic process behind most events leading to winterkill is freezing or formation of ice in plant tissues. There are some stresses occurring during winter time in connection with water, no matter whether in excess or in shortage. Some of these stress factors can increase overwintering of the plant; the excess of water decreases the frost resistance and thanks to this percentage of overwintering plants decreases.

*Winter desiccation* can occur especially in the aboveground parts of the plants, which can dry gradually and die. Damage by dehydration occurs only at a high water saturation deficit (60%–90%). Disproportion between the uptake and output of water occurs because when the temperature falls below 0°C, the uptake of water by the roots is reduced drastically and when the soil freezes water uptake stops almost completely. Seedlings with root-freezing damage showed a reduction in survival and growth (Bigras and Dumais, 2005). Meanwhile, the aboveground parts of the plants continue to lose water even during the heaviest frosts (desiccation by frost) (Tahkokorpi et al., 2007). Transpiration is increased by low relative humidity, direct exposure to sunshine, and wind. Winter desiccation is particularly dangerous late in winter when the soil usually remains frozen and free of snow, while the air temperature increases above zero (Petr, 1991).

Plants are exposed to stress from *flooding* when the topsoil is no longer able to absorb the water after snow thawing or a long rain. Field observations suggest that flooding events in the growing season are more detrimental than in winter (Van Eck et al., 2005). Flooding is frequent in spring when the water from the thawing snow remains standing in the fields. Spring flooding can damage the plants directly and aggravate the damage which was caused by frost in winter.

If in a crop stand where water freezes or if water from melting ice freezes again, *ice sheets* develop. The survival of ice-encased plants depends on temperature, the porosity and thickness of the ice layer, the time for which the plants remain in the ice, and the frost resistance of the plants. The vitality of the plants declines markedly with the thickness of ice up to 20 mm; thereafter there is no decrease in vitality. Damage by ice encasement is ascribed to the toxic accumulation of CO<sub>2</sub> and ethanol which are the products of anaerobic respiration (Gudleifsson, 2009).

The hardening processes can be disturbed by a high soil temperature and by waterlogging of the topsoil. Excess water in topsoil also intensifies the frost injury. On the other hand, the hardening is encouraged if the plant water content is reduced by icy conditions. The trials of Cloutier and Andrews (1984) confirm that a drought stress has a positive influence on the induction of frost hardiness. In trials with winter wheat, water deficit alone partly hardened the plants to about 30% of the level of hardiness that would be induced by low temperature alone. A combination of low temperature with water deficit is the most effective treatment to raise hardiness (Willemot and Pelletier, 1979).

### 11.1.9 PLANT PROTECTION AGAINST LOW TEMPERATURES

There is a chronic and large demand for low cost, effective, and environmentally acceptable cold protection, also referred to as frost protection, techniques in temperate areas around the world to protect orchards (pome fruits, citrus, stone fruits, and nut crops), vineyards, cut flowers, and small

fruits (berries). The protection against freezing employs the unusual properties of water, especially its high heat capacity and high *exothermic heat* released during transition of water to the ice. The release of the latent heat of fusion (e.g., freezing water directly on plant-overtree sprinklers; or on surface under the canopy-undertree sprinklers) protect plants against freezing temperatures.

Most frost protection methods that increase the water vapor content of the air are generally beneficial. Heat from water is more efficient than some other sources because it is released at low temperatures. This is due to replacing radiation losses with the latent heat of condensation. A high dew point is powerful and effective mechanism selectively warms the coldest plant parts and is available for reducing freeze damage to plants.

Frost protection with water can require large volumes of water to be available for short periods of time, which often creates major physical and legal problems for growers. In addition, there may be other significant environmental consequences after thawing. Physically, there are problems because frost requires water deliveries before water is normally required for irrigation and many carrier systems are not ready for irrigation.

Protection against advective (windy) freezes is much more difficult to achieve than protection against radiative freezes. Consequently, most of the systems are practical and effective only under radiation situations. The formation of inversion layers is a benefit and many methods take advantage of an inversion to furnish, trap, and/or recirculate heat. There are many other methods used for protection of trees in the orchards and a combination of these increases the probability of surviving plants (e.g., mixing of the air, convective heating of the air release of the latent heat of condensation e.g., humidification, fogs, and sprinkler).

## 11.2 WATER FREEZING AT ULTRALOW TEMPERATURES

### 11.2.1 GLASS DEFINITION

There is still much about the molecular physics and thermodynamics of glass that is not well understood, but we can give a general explanation of what is thought to be the case. Many solids have a crystalline structure on the microscopic scale. The molecules are arranged in a regular lattice. As the solid is heated, the molecules vibrate about their position in the lattice until, at the melting point, the crystal breaks down and the molecules start to flow. There is a sharp distinction between the solid and the liquid state that is separated by a *first-order phase transition*, that is, a discontinuous change in the properties of the material such as density. Freezing is manifested by a release of heat known as the heat of fusion (Figures 11.9 and 11.10).

Usually, when a liquid is cooled to below its freezing/melting point, crystals form and it solidifies; but sometimes it can become supercooled and remain liquid below its melting point because there are no nucleation sites to initiate the crystallization. If the viscosity rises enough as it is cooled further, it may never crystallize. The viscosity rises rapidly and continuously, forming thick syrup and eventually an amorphous solid. The molecules then have a disordered arrangement but sufficient cohesion to maintain some rigidity. This state is often called an amorphous solid or glass. In biological object we call it the biological glass (Buitink, 2000).

The vitrified state is metastable, which means that it can relatively easily revert back to a liquid and/or cold crystallize to form ice. Systems are particularly unstable during rewarming. Assigns in molecular mobility and energy may be sufficient to allow water molecules to rearrange (relax) and form ice. Vitrification can be achieved in a number of ways but all usually have the end results of increasing solute concentration to a critical viscosity. The viscosity of water at room temperature is about 0.001 Pa s. Thick oil might have a viscosity of about 0.1 Pa s. As a liquid is cooled, its viscosity normally increases, but high viscosity also has a tendency to prevent crystallization. For temperature-induced glasses, the point at which this occurs is called the glass-transition temperature ( $T_g$ ); molecular motion nearly ceases and the liquid becomes a glassy solid.

**FIGURE 11.9** Enthalpy, heat capacity, and viscosity change of liquid, glass, and crystal with temperature. On crystallization, the viscosity changes abruptly from  $\sim 100$  to  $\sim 10^{20}$  Pa s. A solid can be defined as material with a viscosity greater than  $10^{11}$  Pa s.

**FIGURE 11.10** Schematic state diagram of aqueous solution of cryoprotectant.

Glass is actually a supercooled liquid because there is no first-order phase transition as it cools. In fact, there is a *second-order phase transition* between the supercooled liquid state and the glass state, so a distinction between crystallization and glass transition can still be drawn (Zámečník et al., 2003). The transition is not as dramatic as the phase change that takes from liquid to crystalline solids. There is no discontinuous change of density and no latent heat of fusion. The transition can be detected as a marked change in the thermal expansivity and change of heat capacity of the matter. Heat capacity shows a step change at a second-order transition temperature. The glass transition has properties of a second-order transition, but the transition is not well-defined and it occurs over a temperature range.

The temperature at which the glass transition takes place can vary according to how slowly the plant material cools. If it cools slowly it has longer time to relax, the transition occurs at a higher temperature and the glass formed is more dense. If it cools very slowly, it crystallizes, so there is a minimum cooling rate for the glass formation.

A liquid to crystal transition is a thermodynamic; that is, the crystal is energetically more favorable than the liquid when it is below the melting point. The glass transition is purely kinetic, that is, the disordered glassy state does not have enough kinetic energy to overcome the potential energy barriers required for movement of the molecules. The molecules of the glass take on a fixed but disordered arrangement. Glasses and supercooled liquids are both metastable phases rather than true thermodynamic phases like crystalline solids. In principle, a glass could undergo a spontaneous transition to a crystalline solid at any time.

The hypothesis that the glassy states are results of change from being a supercooled liquid to an amorphous solid at the glass-transition temperature, but it is difficult to justify. Polymerized materials such as rubber show a clear glass transition at low temperatures but they are normally considered to be solid in both the glass and rubber conditions. Glass is defined sometimes as being neither a liquid nor a solid. It has a distinctly different structure with properties of both liquids and solids (Figure 11.1).

Viscosity increases rapidly to solidification near  $T_g$ , but over a small temperature range rather than at a precise temperature (in contrast to fusion, which occurs at a precise temperature). The change that happens at  $T_g$  is a rapid increase in viscosity but not a change of state. Viscosity becomes very high near  $T_g$  when cooling from above, which means that  $T_g$  is better characterized as a “rubber/glass transition” than a “liquid/glass transition.” In practice,  $T_g$  occurs within a narrow temperature range because changing a cooling rate an order of magnitude (i.e., by a factor of 10) only changes  $T_g$  by 3°C to 5°C. The situation at the level of molecular physics can be summarized that there are four main types of molecular arrangement of water: water as a liquid, water in vapor phase, as a solid (ice), and finally as a glass (Figure 11.1).

### 11.2.2 PHYSICAL CHEMISTRY OF VITRIFICATION

Three phenomena are necessary for glass transition involvement: dehydration, quench freezing, and quench warming. Water is not very viscous; therefore, it can be vitrified only by an extremely rapid quench freezing of a small sample. Under such rapid cooling, water molecules do not have time to arrange themselves into a crystalline lattice structure. Viscosity increases very little when water is cooled, but at freezing temperature a sudden phase transition occurs to an ice crystal.

In contrary, volume continues to decrease and viscosity continues to increase below  $T_g$ . Because cooling occurs from outside to inside, overlay rapid cooling creates stress when the warmer core needs to contract more than the cooler surface. This may be the reason why slow cooling reduces cracking. Plants are sometimes tearing in to small pieces by cracking. At  $T_g$  there is a sudden increase in viscosity and heat capacity (usually many orders of magnitude), but there is no comparable sudden decrease in volume. The Kauzmann temperature ( $T_k$ , ideal glass-transition temperature) is a hypothetical temperature at which the configurational entropy of a supercooled liquid is presumed to be reduced to that of a crystalline state (Figure 11.9).

11.2.3 CRYOPRESERVATION METHODS

If the freezing rate of cells or tissues is sufficiently slow, less than  $10^{\circ}\text{C min}^{-1}$ , ice is form outside the protoplasts where water is purest. Protoplasmic water will migrate out of the cells and add to the extracellular ice crystals. Extracellular ice does not kill plant cells and the tissues can normally be rewarmed without injury. At intermediate freezing rates ( $10\text{--}100^{\circ}\text{C min}^{-1}$ ), ice crystals are formed within the protoplasts. Intracellular ice formation disrupts the fine structure of the cells and invariably results in death.

How rapidly should plant samples be cooled from  $10^{\circ}\text{C}$  to  $-196^{\circ}\text{C}$ ? Pure water can be vitrified by cooling it at a rate of about 3 million  $^{\circ}\text{C}$  per second to about  $-138^{\circ}\text{C}$ , but this cooling rate is impractical for cryopreservation. The rate of cooling required to produce a vitrified (glassy) state is slower for solutions containing cryoprotectant than for pure water. The rate of cooling which produces glass state is referred as the critical cooling rate.

Vitrification occurs in cells of twigs of some woody plants such as poplar, which could explain why twigs of several woody species can survive the temperature of liquid nitrogen (Sakai, 1960). These findings of biological object vitrification gave a background for further cryopreservation of plants not tolerating extracellular freezing of water (Reed, 2008) (Table 11.3).

Completely ice-free cryogenic storage is the latest approach to plant cryoconservation. The key to developing cryoprotective vitrification strategies is to increase cell viscosity to the point at which ice formation is inhibited and water becomes vitrified after exposure to cryogenic temperatures.

Plantlets may be preconditioned in special media or with specific growth conditions, precultured with cryoprotective chemicals just prior to cryopreservation, and protected with vitrification solutions prior to plunging in to liquid nitrogen.

For glass detection, it is usually used differential scanning calorimeter (DSC) which is used for the direct estimation of glass-transition temperature, ice nucleation temperature, or melting temperature and amount of freezable water (osmotically active water) in a cell or tissues and the percent of the cell volume which is osmotically inactive. Estimate the osmotically inactive fraction of water by the Boyle–van’t Hoff plot (Sun, 1997), which plots a cell volume as the dependent variable and a reciprocal of external osmolality as the independent variable.

Glass-transition temperature is related to the value of  $T_m$  on a Kelvin temperature scale for substances that vitrify:

$$T_g = \frac{2}{3T_m} \tag{11.13}$$

On the Kelvin temperature scale, it is a rule of thumb that  $T_g$  occurs at about two-thirds the value of the melting temperature ( $T_m$ ). Substances for which  $T_g/T_m$  is significantly greater than  $2/3$  are *fragile* (according to the terminology of Angel) (Hancock and Shamblin, 2001). Liquids classified

**TABLE 11.3**  
**State of Water-Influenced Physiological Process during Cryoprotocol**

| Temperature | Water-Dependent Process | Physiological Process                      |
|-------------|-------------------------|--------------------------------------------|
| Pre-cooling | Dehydration stress      | Water removing, osmotic potential decrease |
| Cooling     | Supercooling            | Separation of ice nuclei                   |
|             | Osmotic stress          | Plasmolysis                                |
|             | Desiccation stress      | Solute concentration                       |
|             | Glass transition        | Biological glass formation                 |
|             | Osmotic stress          | Deplasmolysis                              |
| Warming     | Rehydration             | Water equilibrium, growth                  |

as “strong glass formers” show only a small change in viscosity at  $T_g$ , whereas so-called “fragile” liquids such as polymers show very large changes in viscosity at  $T_g$ .

Generally, the glass-forming substances can be divided according to nucleation and growth control as follows:

Poor glass formers:

1. Liquids that quickly form large numbers of nuclei close to  $T_m$ .
2. Crystals that grow very quickly.

Good glass formers:

1. Liquids that are too sluggish to form nuclei even far below  $T_m$ .

In the case of dehydrating processes, water is removed by osmotic dehydration, freeze drying, and/or by the evaporation of water to outside the cells and tissues. This is done mainly by using more concentrated cryoprotectants (mainly mixture of penetrating and non-penetrating cryoprotectants and by slow cooling rate and/or by dehydration in airflow in flow boxes or over a silica gel. Using this method for cryopreservation, other problems arise: sensitivity to cooling rate, desiccation sensitivity rate, and final value of dehydration desiccation sensitivity. The desiccation sensitivity does not depend only on sensitivity to a different rate of desiccation but also on the final level of dehydration. Minimum water or nonfreezing water volume is called “vital” water.

#### 11.2.3.1 Two-Step Freezing Method

In two-step freezing experiments, believed to mimic dehydration stress, protoplasts can undergo reversible contraction-expansion cycles, or osmotic excursions, when slowly cooled and warmed from  $>0^\circ\text{C}$  ( $\psi_w \sim -0.5\text{ MPa}$ ) to temperatures of  $-5^\circ\text{C}$  to  $-20^\circ\text{C}$  ( $-2.5 \geq \psi_w \geq -6\text{ MPa}$ ). A 60%–80% reduction in cell volume occurs when the water potential of cells decreases from about  $-0.5\text{ MPa}$  to about  $-4.5$  to  $-6\text{ MPa}$  ( $-4^\circ\text{C}$  to  $-5^\circ\text{C}$ ) (Meryman, 1974; Steponkus and Lynch, 1989).

Two-step freezing method is mainly used in two steps with different cooling rates (Reed and Uchendu, 2008). In the first step of this method, the plants are cooled to a certain temperature, usually to  $-40^\circ\text{C}$ , by the rate ranging from  $0.25^\circ\text{C min}^{-1}$  for mint to  $2^\circ\text{C min}^{-1}$  (Towill, 2002). Using cell suspension cultures of *Puccinellia distans* derived from callus, it was found that the cooling rates were below  $1^\circ\text{C min}^{-1}$  (Heszky et al., 1990). After reaching desired temperatures (from  $-30^\circ\text{C}$  to  $-40^\circ\text{C}$ , the usual terminal temperature  $-40^\circ\text{C}$ ), the samples are cooled much faster till the liquid nitrogen temperature is reached. The cooling rate in the second part of slow freezing method was as high as possible.

If cooling is too slow, however, cells will be killed by prolonged exposure to low temperature. During the first part of this method time is given to remove water. *Two-step freezing method* is based on slow cooling to a subzero temperature, usually to  $-40^\circ\text{C}$ . During this equilibrium freezing, osmotic equilibrium is established, and then followed by rapid cooling to the liquid nitrogen temperatures. By slow cooling the cells can be killed either by toxic concentrations of electrolytes that form inside the cell or by mechanical crushing from extracellular ice.

#### 11.2.3.2 Cryoprotectants

A colligative property of a solution depends only on the ratio of the number of particles of solute and solvent in the solution, not the identity of the solute. The theory of colligative effect has two essential attributes (Benson, 2008):

1. Cryoprotectants must be able to penetrate the cell, or else they will cause osmotic dehydration and cause the very injury they are used to protect against.
2. Cryoprotectants must be nontoxic to the cell at the concentrations required for their efficacy. Penetrating cryoprotectants make a contribution to the overall osmolality of the cell (Table 11.4).

**TABLE 11.4**  
**The Classification of Main Cryoprotectants according to Their Penetration to the Cells**

| Group of Cryoprotectants                                 | Intercellular Space                                                                | Cell Wall | Plasmatic Membrane | Cytoplasm |
|----------------------------------------------------------|------------------------------------------------------------------------------------|-----------|--------------------|-----------|
| Soluble proteins, polysaccharides, PEG 6000 <sup>a</sup> |   |           |                    |           |

<sup>a</sup> Polyethylene glycol, with molecular weight.

<sup>b</sup> Dimethylsulfoxide.

The glass-transition temperature ( $T_g$ ) is important for cryopreservation of the cryoprotectant/water mixture. For most used cryoprotectants, the glass-transition temperatures as well as critical concentrations are given in Table 11.5. It is possible to divide the cryoprotectants to penetrating and non-penetrating cell wall and plasmalemma (Tao and Li, 1986). Penetrating cryoprotectants have a colligative property in which the salt is buffered down to low temperatures. They are able to cross the cell wall and cell membrane and they buffer the intracellular salt as well.

Non-penetrating cryoprotectants are thought to act by dehydrating the cell at high sub-freezing temperatures. These cryoprotectants help for rapid cooling and glassy state involvement. These compounds are specific with their high molecular weight (generally polymers) that form extensive hydrogen bonds with water, reducing the water activity to a much greater extent than would be predicted by their molar concentration (they do not obey Raoult's law). See the list in Table 11.5 of the main cryoprotectants.

**TABLE 11.5**  
**Glass Transition of Cryoprotectants at Concentration of Cryoprotectants Required to Vitrify**

<sup>a</sup> Dimethylsulfoxide.

### 11.2.3.3 Plant Vitrification Solution

Vitrification solutions involving vitrification were developed in the 1990s (Langis and Steponkus, 1990; Sakai et al., 1990), and the number of cryopreserved species has increased markedly since then. In vitrification procedures, cells and meristems must be sufficiently dehydrated before they are plunged in liquid nitrogen (Langis and Steponkus, 1990). Sakai (1960) used glycerol-based Plant Vitrification Solutions designated 2 (PVS2). PVS2 contains 30% glycerol (w/v), 15% ethylene glycol (w/v), and 15% dimethylsulfoxide (DMSO; w/v) in basal culture medium (without growth regulators) containing 0.4 M sucrose (pH 5.8). Nishizawa et al. (1993) developed Plant Vitrification Solution No. 3 (PVS3) with composition of 50% glycerol (w/v) and 50% sucrose (w/v) in water.

PVS2 easily supercools below  $-100^{\circ}\text{C}$  upon rapid cooling and solidifies into a metastable glass at about  $-115^{\circ}\text{C}$ . Upon subsequent slow warming, plant have a glass-transition temperature ( $T_g$ ) at about  $-115^{\circ}\text{C}$ , with an exothermic cold crystallization at about  $-75^{\circ}\text{C}$  and an endothermic melting  $T_m$  at about  $-36^{\circ}\text{C}$ .

In brief, the cryopreservation procedure has the following steps (Sakai et al., 2008):

1. Preculture of excised meristems on solidified medium with 0.3 M sucrose at room temperature or at  $0^{\circ}\text{C}$ .
2. Osmoprotection with loading solution. Loading with a mixture of 2 M glycerol and 0.4 M sucrose for 20–30 min at  $25^{\circ}\text{C}$ . An osmotic loading treatment increases the osmolarity of the cell and minimizes osmotic damage caused by the vitrification solution.
3. Dehydration with a vitrification solution (PVS2 or PVS3).
4. Rapid cooling/rapid warming.
5. Unloading, dilution of the vitrification solution.

It is evident from these steps that the water relation of cells and tissues is basic for the success of cryopreservation.

### 11.2.4 DEVITRIFICATION

*Devitrification* is interpreted as the transition of a glass into liquid. Sometimes the term devitrification is used for a different type of behavior; it is used for crystallization of water after crossing the glass-transition temperature. For this phenomenon, the usually used term is cold crystallization (Sikora et al., 2007). During warming of rapidly cooled cells, at low temperatures above the glass-transition temperature, the gradient in osmotic pressure driving water from the cell remains. Therefore, the conditions for membrane damage due to water flux persist during warming until the melting of ice reduces and then reverses the movement of water across the membrane. There is evidence that plasma membrane damage due to excessive osmotic pressure creates holes in the membrane, allowing ice to form intracellularly (Muldrew and McGann, 1994). However, warming from the glassy state to temperatures above the  $T_g$  results in a tremendous increase in diffusion, not only from the effects of the amorphous to viscous liquid transition but also from increased dilution as melting of small ice crystals occurs almost simultaneously ( $T_g = T_m$ ). The time scale of molecular rearrangement continually changes as the  $T_g$  is approached, so that food technologists can also gain some enhanced stability at temperatures above  $T_g$  by minimizing the  $\Delta T$  between the storage temperature and  $T_g$ , either by reduced storage temperatures or enhanced  $T_g$  through freezing methods. Hence, knowledge of the glass transition provides a clear indication of molecular diffusion and reactivity and, therefore, ideal state for a long-time saving of biological material in relative stable state.

### 11.2.5 GLASS STABILITY

Glassy status as a common solid/rigid state occurring in biological samples habitually results from a suitable circumvention of crystallization. The quality of glassy state is possible to define simply by ratio ( $T_g, T_m$ )-the lower the ratio, the higher the difference of  $T_g$  and  $T_m$ , a greater stability of glassy

state. A more sensitive interrelation to the glass formation peculiarities can be found on the basis of Hruby coefficient,  $K_g$

$$K_g = \frac{T_c - T_g}{T_m - T_g} \quad (11.14)$$

where  $T_c$ ,  $T_g$ , and  $T_m$  are temperatures of crystallization, glass transition, and melting temperature, respectively. It is clear that the greater the value of  $K_g$ , the better the glass forming. The best utilization of  $K_g$  is in the comparison of glass-forming ability and glassy-state stability of different biological materials under different conditions and thermal treatments. Hruby coefficient ( $K_g$ ) indicates the glass stability against crystallization on heating and can be used to estimate the vitrification ability of glass-forming liquids. Both of these characteristics ( $T_g$ ,  $T_m$ ) are easily measured by conventional differential thermal analysis or DSC during warming samples in glassy state.

The kinetic stability of biological glasses is clearly  $T_g$ -dependent. The reaction rate constants deviate notably from the traditional Arrhenius behaviors and can be well fitted to the Williams–Landel–Ferry (WLF)

$$\log a(T) = \frac{-C_1(T - T_g)}{C_2 + (T - T_g)} \quad (11.15)$$

where  $C_1$  and  $C_2$  are universal WLF constants. It was found that different polymers exhibit very similar WLF constants. The universal values of constants in the WLF equation, used for a broad spectrum of amorphous materials ( $C_1 = 17.44$ ,  $C_2 = 52.1$ ) do not match to biological objects, however, to the dynamic processes of biological material. The derived  $C_1$  and  $C_2$  constants of the WLF equation for seed survival of three species at  $T > T_g$  are: for *Glycine* ~37.5 and 269.8, for *Pisum sativum* 22.3 and 179.2, and for *Phaseolus vulgaris* 22.1 and 183.1, respectively (Sun, 1997).

### 11.2.6 DIFFERENTIAL SCANNING CALORIMETRY

For thermal studies of plant samples in low and ultralow temperatures, Differential Thermal Analysis (DTA) is used. By this analysis, it is possible to measure the difference in temperature between, for example, wet sample and dry sample, to determine beginning of freezing. Thermal analysis uses Differential Scanning Calorimeter (DSC) with its modification as modulation of temperature. By this technique, it is possible to measure heat flow (Figure 11.11)

$$\frac{dQ}{dt} = \frac{C_p dT}{dt + f(t, T)} \quad (11.16)$$

where

$dQ/dt$  is total heat flow ( $W\ g^{-1}$  or  $J\ g^{-1}\ s^{-1}$ )

$C_p$  is specific heat capacity ( $J\ g^{-1}\ ^\circ C^{-1}$ )

$dT/dt$  is heating rate ( $^\circ C\ s^{-1}$ )

$f(t, T)$  is time-dependent response

DSC is used as a main tool in cryobiology to assist cryopreservation protocol development, to control and document cryoprotocols in usage, and to keep information about stored samples and their thermal properties (Zámečník and Šesták, 2009; Zámečník and Šesták, 2010). Water-state

**FIGURE 11.11** Shift of the glass-transition temperature to the higher temperature after dehydration of apple buds (Bilavčík, unpublished).

transitions were detected during the cooling and heating of samples as a function of time and temperature. The main two characteristics: the temperature of glass transition and the amount of frozen water are crucial for cryopreservation (Benson, 2008) (Table 11.6).

**Cryobanking.** The stress physiology of water behavior at low and mainly at ultralow temperature act as put on the vegetatively propagated plants, recalcitrant seeds, and pollen. There are many cryobanks round the world and in comparison to the cryobanking of other biological objects (medical and animal cryobanks), the plant cryobanking is the youngest of all of them.

|        | CA                 | -16                   | -76                 | 2                         | >-196 (48%)           | -20                 | 0.2                       |

*Notes:* Slow cooling rate was 9°C min<sup>-1</sup> after ice seeding at -3°C, quench freezing rate was several orders higher after directly plugging the shoot tip meristems into liquid nitrogen (-196°C) with dehydration pretreatment. CA, cold-acclimated; N-CA, non-cold-acclimated plants; LT<sub>50</sub>, lethal temperature of survival/regeneration after freezing test; T<sub>g</sub>, glass-transition temperature measured by differential scanning calorimetry; H, hydration of shoot tips expressed as the ratio of weight of water to dry weight of plant matter after drying the samples at 105°C (Zámečník, Faltus, and Bilavčík, prepared for publishing); ND—not detected.

### 11.3 CONCLUSION

Plants, during evolution, have developed many mechanisms for how to survive low temperatures. Most of them tolerate high amounts of water in frozen state. Plant-stress physiology at low temperatures describes many mechanisms how plants can avoid, tolerate, or resist all states of water (supercooled water, ice and water in glassy state). Plants combine different strategies to survive low temperature even in one organ. In plant physiology of low-temperature stress, there is still a great amount of unanswered questions. Those that have been answered have a great influence either in technological protection of plants against low-temperature stress or genetic improvements of their cold tolerance.

Plant vitality, after storing them at ultralow temperature, is important for safe biodiversity keeping. Knowledge of water behavior at ultralow temperatures can help plants to survive from “outside.” Many modern cryopreservation methods are based on vitrification. Low water content is the main prerequisite for involvement in the glassy state in plant cytoplasm. On the other hand, the level of dehydration is closed to a vital amount of water and in antithesis in some cases when plants are mildly damaged by dehydration with the aim to increase regeneration after the cryopreservation protocol. From this point of view, the resistance to dehydration is very important for higher regeneration of thawed plants from ultralow temperatures.

## 12.1 INTRODUCTION

Germination of seed and propagules is a complex phenomenon involving many physiological and biochemical changes prior to activation of the embryo and protrusion of the radicle (Bewley and Black 1985, Mayer and Poljakoff-Mayber 1989, Bradford and Nonogaki 2007). During initial stages of germination, propagules, being vegetative tissues, may respond differently to seeds; however, fundamentally, seedlings from both grow similarly. Any unfavorable changes may jeopardize the process of germination (Espinar et al. 2005, Khan and Weber 2008, Wahid et al. 2008).

Salinity, as an abiotic hazard, induces many disorders in seeds and propagules during germination and/or sprouting (Koyro and Eisa 2008, Rasheed 2009). A negative correlation between salinity of substrate and seed germination/vigor has been well established (Rehman et al. 2000). Salinity arrests germination at higher levels and induces a state of dormancy at lower levels (De Villiers et al. 1994, Khan and Weber 2008). Salinity affects imbibition of water due to lowered osmotic potential of germination media (Bliss et al. 1986, Poljakoff-Mayber et al. 1994, Khan and Weber 2008). It also causes toxicity; that is, it changes the activity of enzymes of nucleic acids metabolism (Gomes Filho and Sodek 1988, Guerrier 1988, Gomes Filho et al. 2008), alters protein metabolism (Yupsanis et al. 1994, Dell'Aquila and Spada 1993, Dantas et al. 2007), upsets plant growth regulator balance (Khan and Rizvi 1994), and reduces the utilization of seed reserves (Mondal et al. 1988, Promila and Kumar 2000, Othman et al. 2006). It may cause changes at ultrastructural (Bliss et al. 1986, Koyro 2002), cell and tissue (Valenti et al. 1992, Wahid et al. 1998, Rasheed 2009), and organ levels (Reinhardt and Rost 1995, Rasheed 2009).

Salinity interacts with certain plant and environmental factors during germination. The main plant factors are the seed coat and other sterile seed structures (Eschie 1995, Ahmad et al. 2005, Kaya 2009), dormancy (Khan and Weber 2008), seed age (Smith and Dobrenz 1979, Khajeh-Hosseini et al. 2002, 2003), seed polymorphism (Khan and Ungar 1984a, Khan and Weber 2008), and seedling vigor (Rogers and Noble 1991, Lin and Kao 1995, Kaya and Day 2008). Among environmental factors, temperature (Khan and Ungar 1997a), light (De Villiers et al. 1994), availability of water (Hegarty 1978), oxygen (Wijte and Gallagher 1996a), and influence of other gases (Xu et al. 2006, Zheng et al. 2009) affect seed germination under saline conditions.

This chapter covers some physiological and biochemical aspects of seed germination and propagule sprouting under salinity. Internal (plant) and external (environmental) factors influencing germination of seeds and propagule sprouting in saline media are also discussed.

## 12.2 PROCESS OF GERMINATION UNDER SALINITY

Germination of a viable seed or propagule starts with imbibition of water and terminates with emergence of embryonic tissues. It involves the hydration of proteins, subcellular structural changes, respiration, synthesis of macromolecules, and cell elongation (Bewley and Black 1985, Bradford and Nonogaki 2007). Chong and Bible (1995) regarded growth of embryonic tissues as an important step in the completion of germination, while others emphasized seedling establishment under stressful conditions (Stumpf et al. 1986, Katerji et al. 1994, Akhtar et al. 2003). The latter seems crucial under salinity, as without a successful crop stand simple emergence of embryonic tissues will prove futile. The process of germination is influenced by the nature and extent of salinity and, above all, the behavior of seeds or propagules (Tavili and Biniiaz 2009, Wahid et al. 2009). To better understand the adverse effects of salinity, we have categorized the process of germination into four events: (1) imbibition, (2) active metabolism, (3) emergence and elongation of embryonic tissues, and (4) establishment of seedlings (Table 12.1).

### 12.2.1 IMBIBITION OF WATER

Hydration of stored materials is the initial step for the onset of germination (Katembe et al. 1998). The osmotic component of salinity has a strong inhibitory effect on hydration of the embryo, cotyledon/s, and endosperm (Wahid et al. 1998). It is independent of salinity type and growth media,

**TABLE 12.1**

(1986) and Rogers et al. (1995)                                                                                              |
|                                               | NaCl + Na <sub>2</sub> SO <sub>4</sub> + MgCl <sub>2</sub> + CaSO <sub>4</sub> | Reduced growth, vigor and establishment of seedlings                                                                                                                                                                                                       | Sinha and Gupta 1982                                                                                                                       |

as any salt will induce an osmotic effect (Alam et al. 2003, Tavili and Biniiaz 2009). One study found that seeds of a halophytic shrub (*Atriplex lentiformis*) and a glycophytic species (*Medicago sativa*) imbibed water from a saline substrate in a similar manner, suggesting that initial events of seed germination were similar in both species (Malcolm et al. 2003).

### 12.2.2 ACTIVE METABOLISM IN STORAGE TISSUES AND EMBRYO GROWTH

Upon exposure to saline solutions, ions are inevitably taken up by the seed, which are toxic to various physiological and biochemical processes. The activities of enzymes are hampered (Yupsanis et al. 1994, Yokoishi and Tanimoto 1994), leading to altered and reduced synthesis of micro- and macromolecules (Ben Miled-Daoud and Cherif 1994) and their reduced mobilization to developing

tissues (Wahid et al., 1998, Ben Miled-Daoud and Cherif 1994, Huang and Redman 1995). In *Pinus pinea* seeds, sodium chloride (NaCl) or seawater reduced the activity of isocitrate lyase, malate synthase, phosphoenolpyruvate carboxykinase, and citrate synthase, but NaCl was more damaging (Sidari et al. 2008). Applied salinity increased respiratory rate and ethylene production, enhanced the levels of spermidine and spermine, and reduced putrescine levels in germinating *Lactuca sativa* cultivars. These changes suggest that ethylene, but not polyamines, are a marker of salinity tolerance (Zapata et al. 2003, 2004).

Salinity, applied using NaCl and sodium sulfate ( $\text{Na}_2\text{SO}_4$ ), terminated mobilization of storage lipids by day 8 in cotyledons and day 4 in roots of purple alfalfa seeds during germination and seedling growth (Baranova et al. 2006). Another study focusing on ultrastructural changes in alfalfa cotyledons revealed that an osmotic potential of 607.8 kPa developed using NaCl did not suppress transformation of amyloplasts into chloroplasts and utilization of starch, while  $\text{Na}_2\text{SO}_4$  inhibited development of chloroplasts and starch utilization. Thus, based on these cytological analyses, a model can be developed for the utilization of starch grains and formation of photosynthetic compartments of chloroplasts in the mesophyll of cotyledons (Baranova et al. 2007).

In cashew (*Anacardium occidentale*) nuts, applied salinity delayed seedling growth and mobilization of cotyledonary reserves. It also affected mobilization of proteins prior to breakdown of lipids and starch. Globulin was the predominant storage protein in cotyledons, and its mobilization and seedling establishment was delayed by NaCl. Free amino acids were mainly retained by cotyledons, while partitioning of storage proteins, lipids, and starch to embryonic tissues was delayed (Voigt et al. 2009). Dell'quila and Spada (1993) noted the synthesis of new proteins in response to saline stress in wheat embryos, which disappeared on return to water. This pattern of protein synthesis in alfalfa and metabolism of carbohydrates was attributed to the specific effect of ions on the activities of pertinent enzymes (Yupsanis et al. 1994, Promila and Kumar 2000). Salinity also improved accumulation of soluble sugars, free proline, and soluble proteins in various plant species (Poljakoff-Mayber et al. 1994, Zidan and Elewa 1995). These metabolites are beneficial for embryo growth by reducing osmotic inhibition and providing substrates for elongation of embryonic tissues (Lin and Kao 1996b, Wahid et al. 1998, Thakur and Sharma 2005).

### 12.2.3 EMERGENCE AND ELONGATION OF EMBRYONIC TISSUES

Seed reserves are used for embryo growth and elongation of young tissues, and involve the turnover and *de novo* synthesis of macromolecules. Germinating seeds in saline media exhibited a lowered and delayed production of radicle and plumule (Wijte and Gallagher 1996b, Wahid et al. 1997, Machado Neto et al. 2004). Sodium chloride affects the emergence of young tissues more adversely than other salinity types (Katerji et al. 1994, Wahid et al. 2009). Soybean seeds, subjected to germinate in NaCl solutions, displayed increased  $\text{Na}^+$  and reduced water,  $\text{Ca}^{2+}$  and  $\text{K}^+$  contents, which were the main reasons for reduced growth of embryonic tissues (Khajeh-Hosseini et al. 2002). However, ionic stress induced proline production in the seed, which played an important role in better seed germination and production of embryonic tissues in sorghum (Thakur and Sharma 2005).

### 12.2.4 SEEDLINGS ESTABLISHMENT

A successful crop stand depends on the establishment of young seedlings. Prolonged exposure to substrate salinity results in an extremely poor stand (Mondal et al. 1988) caused by seedling mortality (Wahid et al. 1999). This may be more pronounced in the case of glycophytes owing to their high sensitivity to salinity (Khan and Ungar 1997b). A good stand of *Sorghum halepense* under mild salinity was attributed to the rapid rate of germination (Sinha and Gupta 1982). Plants with more seedling vigor also produced better stands under saline conditions in tepary and navy beans (Goertz and Coons 1991). The vigorous growth of seedlings in relatively sensitive varieties of *Catharanthus roseus* was attributed to proline metabolism under salinity stress (Jaleel et al. 2007). Benmahioul et al. (2009) reported that in

*Pistacia vera*, salinity had no influence on the production of embryonic axes; rather, postgermination mortality was a major factor in seedling survival. In addition, seed germination tendency in euhalophyte *Suaeda salsa* determined final plant density and survival under salinity (Song et al. 2008).

Investigations on three forest coniferous species, *Picea mariana*, *P. glauca*, and *Pinus banksiana*, revealed that seedling emergence in *P. banksiana* was the lowest but *P. glauca* was the most salt sensitive. High concentrations of sodium sulfate caused hypertrophia in all the species, resulting in reduced seedling height, weight, root length, and number of roots in these species (Croser et al. 2001). In Argan (*Argania spinosa*) plants, reduced seedling survival and growth was attributed to ion toxicity as evidenced from symptoms of salt damage on seedlings (Bani-Aameur and Sippl-Michmerhuizen 2001).

## 12.3 SALINITY EFFECTS ON SEED GERMINATION

Salinity substantially reduces seed germination because of its osmotic effects; mineral toxicity also interferes with germination metabolism. The effects of salinity on seed germination are discussed below.

### 12.3.1 GERMINATION AND SALINITY: OSMOTIC AND TOXICITY EFFECTS?

Germination and salinity interaction is often studied on the premise that it has a dual action, that is, osmotic and toxic actions (Norlyne and Epstein 1984). Attempts to separate both components of salinity by using isotonic solutions of salts and nonpermeating osmotica yielded conflicting data (Petrizzelli et al. 1991, Corchete and Guerra 1986). Some regard the osmotic effect as the crippling factor (Rogers and Noble 1991, Debez et al. 2004), whereas most consider ion toxicity to be the noxious component (Gomes Filho and Sodek 1988, Yupsanis et al. 1994, Wahid et al. 1999, Lin and Kao 1996b), or that both components are equally detrimental to germination (Von der Moezel and Bell 1988, Song et al. 2005a, Sebei et al. 2007, Wahid et al. 2009). Wahid et al. (1998) reported that incubation of seeds in salt solution followed by reduced germination in water inferred ion toxicity. The nature and type of salinity may have varying effects on germination due to differences in ion activity. Most reports find more damaging effects of chloride than sulfate ions (Akhtar et al. 2003, Epstein and Bloom 2005, Vicente et al. 2007).

### 12.3.2 METABOLISM OF STORED MATERIALS

Seeds, whether monocots or dicots, contain storage tissues (endosperm and cotyledons, respectively) and an embryo. The nature and extent of stored materials may differ between species. Major stored materials include proteins, sugars, and oils, with smaller amounts of nucleic acids, plant growth regulators, nitrogenous compounds other than proteins, and some nutrients (Bewley and Black 1985). Salt stress hampers the metabolism of stored materials and embryo growth. At the onset of germination, synthesis of enzymes and changes in metabolic pattern are initiated (Khan and Ungar 1997a), but salinity either alters or does not permit synthesis of specific metabolites required for germination (Gomes Filho and Sodek 1988, Guerrier 1988, Yupsanis et al. 1994).

Salinity stress hampers utilization and mobilization of materials required for seedling production by affecting enzymatic activities of seed essential for these reactions (Table 12.2). For instance, wheat seeds treated with increasing NaCl concentrations or decreasing osmotic potential of germination media resulted in increased proline synthesis and decreased protein contents; whereas activities of proline metabolism enzymes initially increased but then decreased and became steady. These changes suggested that proline accumulation cannot be considered as an index of resistance for salinity stress (Song et al. 2005b). This group, in a separate study, reported that activation of the antioxidant system is an important component of salinity tolerance in wheat during germination (Lei et al. 2005).

**TABLE 12.2**  
**Metabolic Changes in Germinating Seeds and Propagules under Salinity Stress**

| Metabolic Activity | Effect of Salinity                                                                                         | References                     |
|--------------------|------------------------------------------------------------------------------------------------------------|--------------------------------|

|                    | Decrease in soluble amino nitrogen                                                                         | Yokoishi and Tanimoto (1994)   |
| Seed minerals      | Reduced levels of macro- and micronutrients in seed                                                        | Koyro and Eisa (2008)          |
|                    | Reduced levels of macro- and micronutrients in bud                                                         | Wahid et al. (2009)            |

### 12.3.2.1 Proteins

Salinity impacts enzyme activity via protein metabolism (Yupsanis et al. 1994, Small and Gutterman 1992). Applied salinity increased protein concentrations in bean (*Phaseolus vulgaris*) cultivars during germination (Dantas et al. 2007). Activity of proteases, which catalyze the turnover and solubilization of proteins to soluble nitrogen in seed, are largely prone to salinity (Bose et al. 1982). Salinity interfered with the incorporation of (<sup>3</sup>H)leucine and (<sup>35</sup>S)methionine during protein synthesis in wheat embryos (Dell'Aquila and Spada 1993, Petruzzelli et al. 1991) and modulated production of a selected group of proteins not synthesized otherwise (Dell'Aquila and Spada 1993). Ramagopal (1990) identified eight new proteins in germinating barley embryos under salt stress and seven during recovery. In two flax (*Linum usitatissimum*) cultivars, soluble protein contents reduced with time, while salt-induced precocity of protein degradation occurred at 200 mM NaCl, reducing availability of proteins to embryonic tissues (Sebei et al. 2007).

### 12.3.2.2 Carbohydrates

Carbohydrates (as starch) are a major component of storage material in some seeds (e.g., caryopses). Amylases mainly regulate carbohydrate metabolism, and their activity is greatly affected by salinity. The activity of  $\alpha$ -amylase is reduced under salinity in a concentration-dependent manner, depressing seedling growth (Lin and Kao 1996a). Greater salt tolerance of sorghum during germination was attributed to enhanced activity of  $\alpha$ -amylase (Promila and Kumar 2000). Salt-treated lentil seeds did not vary in different solute contents; however, activity of  $\alpha$ -galactosidase increased and caused accumulation of sucrose, galactose, and mannose in embryonic tissues (Corchete and Guerra 1986). An accumulation of osmotically active sugars and proline was noted in different plants, which played an important role during and after relief from salinity (Zidan and Elewa 1995, Wahid et al. 1998).

### 12.3.2.3 Lipids

Glyoxysomal enzymes are responsible for metabolism of stored lipids. Salinity exerts an inhibitory effect on glyoxysomal catalase, malate synthase, and iso-citrate lyase, decreasing levels of triacylglycerol, diacylglycerol, and monoacylglycerol, and increasing levels of free fatty acids and polar lipids (Ben Miled-Daoud and Cherif 1994). In two flax cultivars, applied salinity increased linolenic acid contents and linolenic acid-rich molecular species of triacylglycerols (TAGS) and decreased seed germination (Sebei et al. 2007).

### 12.3.2.4 Nucleic Acids

The most important factor in nucleic acid metabolism is changes in the activation and levels of ribonuclease (RNase). Salinity delays *de novo* synthesis and/or activation of RNase in *Vigna* cotyledons due to its toxic effect (Gomes Filho and Sodek 1988). RNase in the cotyledon of cowpea (*Vigna unguiculata*) under salinity stress hydrolyzed and played a protective role in seedling establishment (Gomes Filho et al. 2008). Cotyledonary RNA levels increased slightly during the first day of germination, but subsequently decreased for up to 7 days; however, DNA decreased continuously during this period (Gomes Filho et al. 1983). Petruzzelli et al. (1991) suggested that suppression of nucleic acid biosynthesis in wheat embryos was due to salt-induced inhibition of the incorporation of precursors into nucleic acids.

### 12.3.2.5 Other Organic Compounds

Various endogenous compounds are differentially metabolized during germination and seedling growth. The glycinebetaine, a compatible solute, disappears (Poljakoff-Mayber et al. 1994), exhibits no change (Stumpf et al. 1986), or accumulates as a result of salt-stimulated betaine aldehyde dehydrogenase activity and rescues the seed from the adverse effects of salt (Yokoishi and Tanimoto 1994). Similarly, increased free proline and soluble sugars of seeds or seedlings has a beneficial role (Poljakoff-Mayber et al. 1994, Wahid et al. 1998, Zidan and Elewa 1995, Wahid et al. 2007).

### 12.3.2.6 Seed Minerals

High contents of seed nutrients are vital for germination, but salinity suppresses their role in seed metabolism and seedling production (Gallasch and Dalton 1989). During germination of sorghum caryopses, more potassium (K), calcium (Ca), phosphorus (P), and nitrogen (N) was partitioned into the plumule and radicle as a strategy to tolerate salinity (Wahid et al. 1998). Guerrier (1986) attributed reduced salt tolerance in tomato to its inability to accumulate and transport lower amounts of Ca and K.

## 12.3.3 REPROGRAMMING OF GENE EXPRESSION

Salinity stress tolerance is a multigenic trait and involves the up- and downregulation of many genes (Taiz and Zeiger 2006); although studies reporting patterns of gene expression at seed germination are scarce. In *Amaranthus hypochondriacus*, a cDNA encoding a cysteine protease inhibitor

(*AhCPI*) synthesized a polypeptide of 247 amino acids with a putative N-terminal signal peptide, which had significant homology to other plant cystatins. *AhCPI* gene was constitutively expressed in mature seeds. Although *AhCPI* expression decreased in germinating seeds, it was active in the radicles and hypocotyls of seedlings. The encoded protein regulated seed germination and protected against various abiotic stresses, including salinity, by inducing accumulation of serine-proteinase-type protease inhibitors (Valdes-Rodriguez et al. 2007). Activation of protease inhibitors enhances salt tolerance during germination (Shan et al. 2008). In transgenic Arabidopsis, overexpression of *Zea mays* 12-oxo-phytodienoic acid reductases (*ZmOPRI*) conferred tolerance against high salt stress during germination in roots but hardly in leaves (Gu et al. 2008).

## 12.4 GERMINATION OF PROPAGULES UNDER SALINITY

The initial events of propagule germination may differ from seeds since propagules are vegetative and seeds are reproductive. However, bud sprouting, elongation, and seedling establishment appear similar. The rate and percentage of germination of sugarcane nodal buds (stem cuttings) significantly decreased in response to NaCl damage (Wahid et al. 1997, Akhtar et al. 2003). These plants had more Na<sup>+</sup> and Cl<sup>-</sup>, and a concomitant reduction in potassium, calcium, nitrogen and phosphorus, reduced elongation, and less seedling dry matter. Histological studies revealed that sprouting buds depicted an array of changes during transition from undifferentiated until the complete differentiation of mesophyll and vascular tissues under salinity stress (Rasheed 2009). In a recent study, Wahid et al. (2009) found a positive correlation between essential nutrient contents in nodal buds of sugarcane genotypes and salinity tolerance at sprouting and during seedling growth.

There is a dearth of information about salt tolerance of propagules during germination. Citrus rootstocks used to raise plantlets under salinity had a negative correlation of Cl with certain endogenous nutrients (Gallasch and Dalton 1989). Resting buds of salt-stressed poplar plants, grown in vitro, did not accumulate glycinebetaine and proline, reducing seedling growth (Bray et al. 1991). Similarly, tubers of hydrilla had signs of salt damage and reduced germination (Stewart and Van 1987). In some potato species and cultivars, studies involving micropropagation of axillary buds in the presence of NaCl significantly reduced shoot length and fresh weight of sprouts (Donnelly et al. 2007).

## 12.5 REGULATION OF IONS IN SEEDS AND SEEDLINGS

Exposure of seeds or seedlings to salinity results in an influx of ions with the imbibition of water, which has an adverse effect on embryo growth (Poljakoff-Mayber et al. 1994). This may lead to a marked decrease in the internal potassium concentration (Petruzzielli et al. 1991, Nichols et al. 2009), a vital nutrient for protein synthesis and plant growth (Epstein and Bloom 2005). Seedlings exposed to salinity are highly prone to excessive ions, sometimes leading to their death shortly after emergence (Wahid et al. 1999, Ahmad et al. 2005). The ability of plants to cope with ion toxicity is principally related to the greater transport of ions to shoots. Grasses tolerate salt by storing toxic ions in the mesocotyl up to a certain limit (Drew and Lauchli 1987, Wahid et al. 1998). As a result, the epicotyls and hypocotyls avoided ion toxicity, thus ensuring better growth (Wahid et al. 1998, Fardus 2006).

## 12.6 STRUCTURAL CHANGES IN SEEDS AND SEEDLINGS UNDER SALINITY

Salinity triggers structural changes at various levels of organization in seeds and seedlings (Table 12.3). At the subcellular level, major changes were found in (1) nuclear chromatin, which was condensed suggesting suppressed nucleic acid biosynthesis, (2) formation of small provacuoles instead of a single large vacuole, and (3) damaged mitochondrial apparatus and reduced oxygen uptake (Bliss et al. 1986, Petruzzielli et al. 1991). Salinity caused contraction of the plasmalemma away from cell walls (Petruzzielli et al. 1991) due to disaggregation of intramembranous particles (Bliss et al. 1984). The cell wall of salt-treated cotton roots and sorghum mesocotyl thickened considerably (Reinhardt and Rost 1995, Wahid et al. 1998).

**TABLE 12.3**  
**Salt-Induced Changes in Anatomical Characteristics in Seeds and Embryonic Structures during Germination**

| Level of Organization | Salt-Induced Change                                                     | References                |

| Tissue                | Constriction of cortical tissue of mesocotyl                            | Wahid et al. (1998)       |
|                       | Increased lignification of secondary tissues                            | Valenti et al. (1992)     |
|                       | Reduction in size of perisperm in embryo                                | Koyro and Eisa (2008)     |

At cell and tissue levels, salinity stress reduced the cortical cell area and, as a result, the mesocotyl of sorghum was considerably constricted and appeared to act as a repository for ions (Wahid et al. 1998). In cotton, an exodermis with a casparian band containing suberin lamellae closer to the root base and in the transition zone of the hypocotyl was induced (Reinhardt and Rost 1995). This protected the loss of water or solute leakage from roots, which was important for osmotic adjustment. Salinity also stimulated development and lignification of secondary tissues and enhanced the number of water-storage cells in the epidermis and cortical layer of the hypocotyl (Valenti et al. 1992).

## 12.7 FACTORS INTERACTING WITH SALINITY DURING GERMINATION

There are various internal (plant) and external (environmental) factors that affect seed germinability under saline conditions, which are discussed below.

### 12.7.1 PLANT FACTORS

The most important plant factors affecting germination under saline conditions are the seed coat, dormancy, seed vigor, and age.

#### 12.7.1.1 Seed Coat and Seed Coverings

The seed coat is the first barrier to the entry of water and ions into the seed. The hard and thick seed coat causes a state of dormancy and restricts entry of water into the seed, minimizing contact of ions with the embryo (Taiz and Zeiger 2006). It also acts as a buffering agent to ionic toxicity (Poljakoff-Mayber et al. 1994, Eschie 1995) and enhances germination. The role of seed coverings exposed to salinity at germination depends upon the plant species under investigation. In cases where the seed coat offers no barrier to the movement of ions and water, it may accumulate toxic ions, minimizing their access to the embryo. For example, seeds of *Acacia tortilis* and *A. coriacea* accumulated more Na<sup>+</sup> in the seed coat and leaked less K and Ca from the embryo (Rehman et al. 1998).

In contrast, the hull on the achene of sunflower played no role in salinity tolerance during germination (Kaya 2009). In *A. portulacoides*, the presence of bracteoles inhibited germination, particularly with increasing salinity. The bracteoles appeared to induce some sort of dormancy, thus crippling germination (Redondo-Gomez et al. 2007).

#### 12.7.1.2 Dormancy

One of the primary impacts of salinity is the induction of dormancy in the seed either from inhibition of nucleic acid synthesis (Khan 1971) or plant growth regulator imbalance (Khan and Rizvi 1994). Although dormancy has no consistent relationship with salinity (Cruz et al. 1995), it is important for halophytes since it permits the seed to remain viable until the environment becomes conducive to germination (Fenner 1985, Khan and Ungar 1997a). Wetson et al. (2008) reported that the state of dormancy induced by salinity and low seed temperature of *Suaeda maritime* was released when the temperature increased to about 15°C and salinity was also reduced.

#### 12.7.1.3 Seed Age

Aging or prolonged storage of seeds affects their germinability (Schoettle and Leopold 1984). This has been used to test and predict salt-tolerance potential during germination. In alfalfa, a strong negative relationship existed between salt tolerance and seed age in a sensitive genotype; but there was a significant decline in solute leachate during imbibition of water in a tolerant genotype (Smith and Dobrenz 1979). In soybean, seed vigor was a major factor in the recovery of aged seeds during germination from salinity stress (Khajeh-Hosseini et al. 2003).

#### 12.7.1.4 Seed Polymorphism

Seed polymorphism, in terms of color, size or mass, has adaptive value in the germination and subsequent life cycle of numerous plants species especially halophytes (Khan and Weber 2008). For instance, seed size of two halophytes, *Salicornia europaea* and *A. triangularis*, was proportional to salt tolerance. In the same saline medium for germination, small seeds had more toxic ions and less reserves per unit weight, which led to more dormancy-delayed germination and reduced weight of seedlings than larger seeds (Khan and Ungar 1984a,b, Ungar 1987). Likewise, in the genus *Frankia*, larger seeded species germinated better under salinity than those with smaller seeds (Easton and Kleindorfer 2009). In contrast, small seeds of the glycophytic sunflower germinated and grew more rapidly in saline conditions than large seeds (Kaya and Day 2008).

Seed polymorphism, in terms of color, size, or mass, has adaptive value in the germination and subsequent life cycle of numerous plants species especially halophytes (Khan and Weber 2008). For instance, seed size of two halophytes, *Salicornia europaea* and *A. triangularis*, was proportional to salt tolerance. In the same saline medium for germination, small seeds had more toxic ions and less reserves per unit weight, which led to more dormancy-delayed germination and reduced weight of seedlings than larger seeds ((Khan and Ungar 1984a,b, Ungar 1987). Likewise, in the genus *Frankia*, larger seeded species germinated better under salinity than those with smaller seeds (Easton and Kleindorfer 2009). In contrast, small seeds of the glycophytic sunflower germinated and grew more rapidly in saline conditions than large seeds (Kaya and Day 2008).

In addition to seed size, seed color has an adaptive value in salt tolerance. In *Suaeda splendens*, brown-colored seeds germinated and survived in a highly saline environment better than black-colored seeds (Redondo-Gomez et al. 2008). Likewise, dark-green-colored seeds of pea germinated better in saline conditions than light-green-colored ones (Atak et al. 2008).

#### 12.7.1.5 Seed and Seedling Growth and Vigor

Seed vigor incorporates properties of the seed that determine the performance of the seed or a seed lot during germination and seedling emergence (Sun et al. 2007). Healthy and vigorous seeds display better germination and seedling growth, which is important for the establishment of plants in the field. As for seedling vigor, root growth, being the most important factor, determines the

establishment of a stand under salinity (Lin and Kao 1996a, Coons et al. 1990). This problem may be partially solved either by using a higher seed rate to obtain high seedling density or by selecting crops for high seedling vigor, especially in arable farming (Rogers and Noble 1991).

### 12.7.2 ENVIRONMENTAL FACTORS

Environmental factors influencing germination include temperature, light, water, and gases.

#### 12.7.2.1 Temperature

A slight variation in temperature can have a major impact on germination. The adverse effect of high salinity is further aggravated by higher temperature regimes, which prolonged seedling emergence in some halophytic plants (Khan and Ungar 1996, 1997a, El-Keblawy and Al-Rawai 2005) or completely inhibited seed germination in the xerohalophyte *Reaumuria vermiculata* (Gorai and Neffati 2007). However, moderate temperatures were more favorable to germination in *Panicum turgidum* (Al-Khateeb 2006). Seed germination of *Limonium stocksii*, exposed to 200 mM NaCl or more, was not affected at moderate (20°C–30°C) temperatures, but was inhibited at lower (10°C–20°C) or higher (25°C–35°C) temperatures (Zia and Khan 2004). Likewise, germination percentage in three euhalophytic species severely declined at the lowest (10°C) and highest (35°C) temperatures under 500 mM level of NaCl (Song et al. 2006).

#### 12.7.2.2 Light

Light has a profound effect on the germination of many species (Agami 1986). Light may be effective in breaking dormancy and promoting germination in some halophyte species. For instance, seeds kept in complete darkness germinated poorly under salinity than those kept in 12 h light/dark periods in *Aeluropus lagopoides*, *Halopyrum mucronatum*, *Sporobolus ioclados*, and *Urochondra setulosa* (Khan and Gulzar 2003), and *L. stocksii* (Zia and Khan 2004). This may result in better stand establishment in marginally saline areas (De Villiers 1994, Khan and Ungar 1997a).

#### 12.7.2.3 Water

Applied salinity is intricately linked to water availability and seed germination. Salt-induced lowering of water potential in the germination medium enhances toxicity, whereas scarcity of water further aggravates it (Atak et al. 2006). Reduced moisture contents in germination media coupled with high ionic strength leads to a differential pattern of protein synthesis (Petruzzelli et al. 1991, Dantas et al. 2007), delayed or inhibited emergence of embryonic tissues (Sinha and Gupta 1982, Yildirim and Güvenç 2006), and a decrease in final rate and percentage, and index of germination (Miyamoto et al. 1982, Mahdavi and Sanavy 2007). Incidental availability of water to salinity-stressed seed can improve seed germination until there is no permanent damage to embryo. This happens because the ionic toxicity is minimized (Redman 1974, Badger and Ungar 1989, Abbassi and Koocheki 2008).

#### 12.7.2.4 Gases

Availability of gases including oxygen (O<sub>2</sub>), carbon monoxide (CO), and nitric oxide (NO) can affect seed germination under salinity. Salt-induced dormancy reduces the availability of oxygen to the embryo for metabolic activities. High salinity coupled with hypoxia significantly reduces both emergence and elongation of the radicle and plumule (Wijte and Gallagher 1996a). Anoxia completely restricted the process of germination; however, no specific difference was discernible with respect to salinity and anoxia tolerance. *Spartina alterniflora* better tolerated salinity and anoxia than *Phragmites australis*, due to its more rapid rate of coleoptile and mesocotyl growth (Wijte and Gallagher 1996b). Use of increased concentrations of hematin as CO donor improved wheat seed germination under salinity by improving antioxidant activities and reducing lipid peroxidation and degradation of seed reserves (Xu et al. 2006). Likewise, soaking wheat seeds in 0.1 mM of sodium nitroprusside (SNP; as NO donor) for 20 h improved seed germination at

300 mM NaCl (Zheng et al. 2009). This action of NO in improving seedling emergence in *Suaeda salsa* was due to signaling property of NO in activating seed-dormancy-breaking genes induced by salinity stress (Song et al. 2009).

## 12.8 CONCLUSION

The events of germination, from imbibition of water to seedling establishment, are all adversely affected by increased levels of salinity. Salinity hampers the rate and percentage of germination, partially through the osmotic effect on imbibition of water and is mainly due to its toxicity to the metabolism of seed reserves. Endogenous nutrient concentrations in seeds and propagules are important for their salinity tolerance. Salinity also induces structural changes at subcellular, cellular, tissue, and organ levels and affects the rate of respiration, transport of materials, and induction of new tissues in seeds or seedlings. As a multigenic trait, salinity alters the expression of a number of genes which are helpful in improving salinity tolerance in germinating seeds. Changes in enzymatic activities may be another important factor in modulating seed germination.

Certain internal and external factors substantially interact with germination and seedling growth under salinity. The seed coat minimizes access of ions to the embryo. Dormancy allows halophytes to escape the adverse effect of salinity. Aging has been used to test seed viability and to predict salt-tolerance ability. Larger seeds tend to have better germination and seedling vigor because of a higher content of seed reserves and lower absorption of toxic ions per unit weight. Likewise, seed color has been found to be related to salinity tolerance in a few plant species. Hard and tough seed coats and seed coverings inhibit seed germination. Salinity-induced dormancy creates an anoxic condition and inhibits seed germination. Scarcity of water, prevailing higher temperatures, and absence of light, all affect seed germination and production of embryonic structures. The seeds with high vigor produce stout seedlings, which are better able to withstand saline conditions and produce better stands in the field.

### 13.1 INTRODUCTION

People on earth are alive because functional and structural proteins in their bodies are made of nitrogen (N) derived from plant or animal food. A great proportion of this N has its origin in fertilizers used in modern agriculture that evolved significantly during the green revolution. The invention of the N fertilizer was possible due to the greatest scientific contribution of Fritz Haber, who discovered the method to convert nonreactive atmospheric nitrogen to reactive N in the form of ammonia (Smil 1997). This process has now significantly influenced the global N balance and has placed agroecosystems in a precarious condition, as fertilizer N is significantly contributing to pollution of aquifers, accumulation of greenhouse gases (Stern Review 2006, Schlesinger 2009), and depletion of the atmospheric ozone layer (Majumdar 2005). In addition, recent trends in the cost of fertilizers have led to a rise in the cost of food production.

Much of the concerns about N fertilizers emanate from the fact that only a fraction of applied N is utilized by crop plants. Persistent research efforts for reduced use of reactive N in agriculture have led to innovative agronomic practices that comprise slow-releasing N fertilizers and precision farming (Cassman et al. 2002). Organic farming is being increasingly proposed as another option to protect the environment. However, if all farmers adopt organic farming, the food produced will not be sufficient to feed the global population, as natural N<sub>2</sub> fixation and organic N recycling cannot keep pace with the N demand of high-yielding crop cultivars (Smil 1997). On the other hand, recent studies with simulation modeling reveal that the N balance tends to be negative in areas such as Indo-Gangetic plains that are being subjected to intensive agriculture mostly with rice and wheat rotation (Pathak et al. 2006). Hence, it is predicted that the next few generations of humankind will continue to depend on reactive N generated in fertilizer factories (Smil 1997). Thus, there is an urgent need for the development of a comprehensive approach to optimize reactive N utilization in every sphere of life. This can be accomplished to a considerable extent by managing the N fertilizer (Ju et al. 2009) and improving the nitrogen use efficiency (NUE) of crop plants through a combination of genetic improvement and agronomic approaches (Delmer 2005, Doberman 2006, Hirel et al. 2007).

The challenges associated with N and the need for improved nutrient efficiency have been emphasized in a few recent reviews (Pathak et al. 2008, Garnett et al. 2009, Townsend and Palm 2009). In an earlier review on NUE, Cassman et al. (2002) addressed the global challenge of meeting increased food demand and protecting environmental quality in cropping systems that produce maize, rice, and wheat. Quantitative understanding of current levels of N use, efficiency and losses in these systems, the biophysical controls on these factors, and the economic returns from adoption of improved management practices were highlighted in this review for setting the research agenda and developing effective policies. Pathak et al. (2008) have summarized the physiological, biochemical, and molecular aspects of NUE, quantitative trait loci (QTL) mapping studies, as well as transgenic efforts to improve NUE in crops and model plants. They also listed the transgenes used for improving NUE and its components. Garnett et al. (2009) elaborated root-based approaches for improving NUE by focusing exclusively on N uptake mechanisms at the root level, and also discussed the scope for molecular intervention.

The objective of this chapter is to present an overview of the present status of N utilization in agriculture, NUE including the process and magnitude of loss of applied N, progress in improving NUE, and strategies and opportunities for genetic improvement of NUE in crop plants.

### 13.2 PRESENT STATUS OF N FERTILIZER USE

The global N consumption has now crossed 100 million tons (Mt) (Heffer and Prud'homme 2008), with more than 50% of it being consumed by Asian countries (FAO 2008). It is estimated that 53.0Mt of N was applied to cereals in 2006–2006/2007, representing 55.3% of global fertilizer N consumption (Heffer 2009). Wheat and maize both contribute to 17.3% of the global use, followed

by rice (15.8%). Other cereals receive 4.6% of the fertilizer N. Oil crops are minor consumers of the N fertilizer, with a market share of 6.3% (6.0Mt of N), rapeseed/canola being the main consumer. Cotton and sugar crops represent 3.8% and 3.3% of the global fertilizer N consumption, respectively. Fruits and vegetables account for 15.3% of the total, and other crops account for 15.9% (Heffer 2009).

It is expected that fertilizer consumption in Africa and Latin America will increase substantially in the future. However, crops in a large proportion of land in these regions will remain undernourished. Hence, increased productivity with less application of the N fertilizer in general and enhanced productivity with no or marginal application of N in low-N-consuming regions are inevitable options for increased production in the future. Some of the fertilizer N applied in one crop season is retained in the organic matter of the soil and will be available in the subsequent crop season (Westerman and Kurtz 1972).

### 13.3 NITROGEN USE EFFICIENCY

#### 13.3.1 DEFINITION

NUE is measured in various ways, for example, the average yield produced per unit of N applied, the quantity of extra N contained in the crop per unit of N applied, or the extra yield produced per unit of N taken up by the crop (Buresh et al. 2007, Sylvester-Bradley and Kindred 2009). All of these ratios can be used as measures of the efficiency with which N is used. NUE is a term used to indicate the relative balance between the amount of fertilizer N taken up and used by the crop versus the amount of fertilizer N “lost.”

#### 13.3.2 PRESENT STATUS OF NUE IN CROP PLANTS

Achieving synchrony between N supply and crop demand is the key to optimizing trade-offs among yield, profit, and environmental protection in both large-scale systems in developed countries and small-scale systems in developing countries (Cassman et al. 2002).

Setting the research agenda to synchronize N supply and crop demand without excess or deficiency requires a quantitative understanding of current levels of NUE and losses in these systems. Based on global consumption and N removed by grains, Raun and Jounson (1999) estimated that the world cereal grain NUE is about 33%; however, a wide range of NUE values have been reported for different crops under different agroecological environments (Table 13.1).

#### 13.3.3 MECHANISMS OF LOSS OF FERTILIZER N

The N supply is determined not only by the applied fertilizer but also influenced largely by the type of soil, the microenvironment of the rhizosphere, and various mechanisms by which the applied fertilizer is lost into the environment. On the other hand, crop demand is determined by the genotype and its growth environment, for example, the levels of radiation and soil moisture. The two predominant N loss mechanisms that commonly occur are leaching and denitrification of the nitrate-N. Nitrogen loss due to the volatilization of surface-applied urea-based products is a third source of N loss for some fields. Surface runoff, particularly during heavy precipitation immediately after fertilizer application, can also lead to significant N loss. It has also been shown that substantial N is lost in the form of  $\text{NH}_3$  from aerial parts of crop plants. Major mechanisms of loss of N are described in brief in Sections 13.3.3.1 through 13.3.3.6.

##### 13.3.3.1 Leaching of Nitrate-N

All applied N fertilizer sources eventually convert completely into the nitrate-N form. This form of N is not held tightly by soil particles and can be leached from the soil profile with excessive rains,

(1997)        |

especially on lighter-textured soils. Nitrate-containing fertilizers, including liquid urea-ammonium-nitrate (UAN) solutions and ammonium nitrate, are susceptible to leaching loss as soon as they are applied. Urea can be converted to nitrate-N in less than two weeks in late spring, and, thereafter, is susceptible to leaching loss. Anhydrous ammonia is converted more slowly to nitrate-N because of its initial toxic effects on the soil microbes that are responsible for the conversion of ammonium-N

to nitrate-N. Loss of N due to leaching alone may be as high as  $36 \text{ kg ha}^{-1} \text{ yr}^{-1}$  in hillside agriculture with a slope of 7% (Zhu et al. 2009).

#### 13.3.3.2 Denitrification of Nitrate-N

Certain soil bacteria that thrive in saturated (anaerobic) soil conditions convert nitrate-N to oxygen and N gases. The volatilization of N gas can result in N losses of as much as 5% of the available nitrate-N per day (Hoeft 2004). Soils at greatest risk to denitrification are those that are naturally heavy and poorly drained, plus fields with significant levels of soil compaction that restricts natural drainage. Because denitrification affects nitrate-N, the relative risk of N fertilizer products is identical to that for loss of N due to leaching.

#### 13.3.3.3 Volatilization of Urea-Based Products

Urea-based N fertilizer products are susceptible to volatilization losses of N if surface-applied and not incorporated. Urease enzymes in the soil and plant residues convert the urea component to free ammonia gas. If this conversion occurs at the soil surface and is accompanied by warm sunny days, as much as 15%–20% of the urea-based N may volatilize within a week after application (Bundy 2001). If a half inch or more of rain occurs within the first 24 h after surface application, the risk of subsequent volatilization also drops to essentially zero (Bundy 2001). If the urea-based product is injected or mechanically incorporated after application, the risk of volatilization is essentially zero. Forms of N fertilizer susceptible to volatilization losses include dry urea or liquid UAN solutions that are surface-applied without incorporation. The risk of volatilization loss is greatest with high-residue cropping systems, warm sunny days after application, and surface soil pH levels greater than 7.0. In some soils, volatilization loss is highly temperature dependent (Liu et al. 2007). Volatilization risk is also high on lighter-textured soils with a low buffering capacity (Griggs et al. 2007).

#### 13.3.3.4 Nitrogen Immobilization

This N loss mechanism is more temporary in nature. Soil microbes that decompose high carbon-content plant residues to organic matter use soil N during the decomposition process (Killpack 1993). Consequently, the N from the surface-applied fertilizer is “tied up” in the resulting organic matter and is temporarily unavailable for plant uptake until mineralization of the organic matter occurs at a later date. Such immobilization of soil N can be especially prevalent in high-residue no-till cropping systems.

#### 13.3.3.5 N Loss through Aerial Part of Crop Plants

Cereal plants release N from plant tissue, predominantly as  $\text{NH}_3$  following anthesis (Francis et al. 1993). Plant N losses have accounted for 52%–73% of the unaccounted 15% N in corn (Francis et al. 1993), and between 21% (Harper et al. 1987) and 41% (Daigger et al. 1976) in winter wheat. Gaseous plant N loss in excess of  $45 \text{ kg N ha}^{-1} \text{ yr}^{-1}$  has also been documented in soybean (Stutte et al. 1979).

The 90 day average plant emission of  $1.8 \text{ mg N m}^{-2} \text{ day}^{-1}$  represented a crop loss of  $1.6 \text{ kg N ha}^{-1}$  and 3.1% of the total N in the wheat plant contained in the chamber (O'Deen and Porter 1986).

The influence of different physiological and environmental parameters on  $\text{NH}_3$  exchange between plants and the atmosphere was reviewed by Schjoerring (1998, 2000). A central parameter in controlling the rate and direction of  $\text{NH}_3$  fluxes is the  $\text{NH}_3$  compensation point. It may vary from below 1 to over  $20 \text{ nmol NH}_3 \text{ mol}^{-1} \text{ air}$ . High compensation points seem to be a result of high tissue N status, rapid absorption of  $\text{NH}_4^+$  from the root medium, and/or low activity of glutamine synthetase, a key enzyme in  $\text{NH}_4^+$  assimilation. These conditions cause the  $\text{NH}_4^+$  concentration in leaf apoplast and leaf cells to increase. The  $\text{NH}_3$  compensation point also depends on the plant developmental stage with peaks in  $\text{NH}_3$  emission related to leaf senescence and N remobilization. The leaf temperature has a profound influence on the  $\text{NH}_3$  compensation point: an increase in temperature from  $15^\circ\text{C}$  to  $30^\circ\text{C}$  may cause a plant to switch from being a strong sink for atmospheric  $\text{NH}_3$  to being a

significant  $\text{NH}_3$  source. Stomatal conductance for  $\text{NH}_3$  relative to that of water vapor increases with the tissue N status and with leaf senescence. At a given leaf temperature, the  $\text{NH}_3$  compensation point can be successfully predicted on the basis of pH and  $\text{NH}_4^+$  concentration in the apoplast of the mesophyll cells. A study conducted with entire plants of spring wheat (*Triticum aestivum*) from tillering to maturation has revealed that the maximum emission of  $\text{NH}_3$  from a plant occurs during ear emergence to grain-filling period (Rroço and Mengel 2000).

#### 13.3.3.6 Factors Influencing N Loss

Nitrogen loss potential is influenced primarily by the type of crop (Cassman 2002), the type of N fertilizer applied (Nielsen 2006), the method of fertilizer application (Limon-Ortega et al. 2000, Lopez-Bellido 2006, Stevens et al. 2007, Barbieri et al. 2008, Rochette et al. 2009), the amount of applied fertilizer (Buresh et al. 2007), the type of soil (Wan et al. 2009), and the crop season (Vaio et al. 2008). Rainfall, sunshine, and temperature all influence the rate of volatilization of surface-applied urea-based products. The timing and amounts of rainfall influence the rates of leaching and denitrification losses of available nitrate-N.

The time of application of the fertilizer during crop growth plays a crucial role in determining the amount of N utilized. Dry matter and N accumulated by winter wheat (*Triticum* spp.) plants until anthesis are of importance under a Mediterranean climate, because the yield greatly depends on the translocation of pre-anthesis assimilates to the grain (Papakosta and Gagianas 1991). NUE of crops such as rice under irrigated condition can be affected by the form of N fertilizer used (Duan et al. 2007).

### 13.4 PROGRESS IN IMPROVING NUE OF CROP PLANTS

All the factors that influence the loss of fertilizer N and also the potential of crop to utilize the applied N across time and space determine the extent and possibility of enhancing N utilization by crop plants. Improved NUE can be achieved by fertilizer management that enhances fertilizer use efficiency by crop and also by improving the genetic potential of plants to take up and utilize the applied N. A lot of efforts have been devoted to improve the N fertilizer management that has shown great potential to reduce the N use without affecting the yield substantially under given conditions (Cassman 1998, Buresh 2007, Buresh et al. 2007). Recently, the improvement of the genetic potential of crops for N use is gaining importance. This can be achieved by a proper understanding of NUE components.

#### 13.4.1 COMPONENTS OF NUE

Numerous processes are involved in NUE in crop plants, and the concept for evaluating the contribution of N uptake and utilization processes to the variation in NUE have been developed and demonstrated in corn (Moll et al. 1982).

NUE is a complex trait. Moll et al. (1982) and Ortiz-Monasterio et al. (1997) showed that NUE comprises the N uptake efficiency (UPE) and the N utilization efficiency (UTE), the latter of which can be further split into biomass production efficiency (BPE) and harvest index (HI).

#### 13.4.2 GENETIC VARIABILITY FOR NUE IN CROP PLANTS

The recent plateau in the yield potential trend of majority of staple crops now has set high demands on plant breeders to develop cultivars not only with increased yield potential but also with higher NUE, thereby combining the improved ability to absorb N more efficiently from the soil with efficiency in utilizing it for biomass production and grain yield (GY).

Variability in NUE or its components between the crop plants and within the crop plants has been reported. A comparison of N harvest index (NHI) and N remobilization efficiency (NRE)

revealed that both were low for wheat, linking this with high N uptake after anthesis, suggesting that in wheat the proportion of the assimilated N used immediately in the developing grain is greater than in barley and oat. There was no strong N translocation from vegetative parts of the main shoots in wheat, which exhibited higher competition for N between vegetative and reproductive organs (Muurinen et al. 2007). This is in contrast with the earlier observations that in wheat, 60%–95% of the grain N comes from the remobilization of N stored in roots and shoots before anthesis (Palta and Fillery 1995, Habash et al. 2007). This might be due to the complexities associated with the type of soil and growth environments in which these experiments were conducted.

Genetic variability in NUE has been reported in maize (Moll et al. 1982, Coque and Gallais 2007), rice (Samonte et al. 2006, Duan et al. 2007), barley (Anbessa et al. 2009), canola (Gan et al. 2008), wheat (Brancourt-Hulmel, et al. 2003), and sorghum (Traore and Maranville 1999).

Results from experiments have shown genetic variation in cereals for UPE (Kelly et al. 1995, Singh and Arora 2001) and for UTE (Woodend et al. 1986, Papakosta 1994, Singh and Arora 2001). For wheat, UPE accounts for most of the variation in NUE at low N availability (Ortiz-Monasterio et al. 1997, Le Gouis et al. 2000). Recent results obtained under northern growing conditions showed that UPE has a stronger relationship with NUE than UTE (Muurinen et al. 2006). However, there were indications of differences between cereal species in their NUE to UTE relationship. The association was especially strong for oat (Muurinen et al. 2006), which occurs, as also noted by Isfan (1993), regardless of N supply. Furthermore, Delogu et al. (1998) showed that in low-N-input environments, winter barley had higher UTE than winter wheat and UTE was also associated with higher NHI. This indicates the retranslocation efficiency of N from vegetative plant parts to the grain. Many studies have indicated that 70% or more of the N harvested in seeds is derived from N remobilized from senescing vegetative plant parts (Austin et al. 1977, Cox et al. 1985, Papakosta and Gagianas 1991). Therefore, an improved understanding of plant N requirements and dynamics, particularly, BPE (biomass partition efficiency) and NRE (nitrogen remobilization efficiency) from vegetative parts among species and cultivars, is needed to determine better NUE.

### 13.4.3 GENETIC IMPROVEMENT

#### 13.4.3.1 Conventional Plant Breeding

Because the agronomic NUE is defined as the ratio of GY to N supplied (by soil and fertilizer), the GY potential under a given fertilizer level determines the NUE. Hence, breeders empirically select those that are more efficient in terms of N absorption and utilization. As modern maize genotypes were selected in the presence of high fertilization, they were consequently selected for their adaptation to a high input (Castleberry et al. 1984), though this assumption has been contradicted by results obtained in experiments with old and modern cultivars of wheat (Ortiz-Monasterio et al. 1997). However, the expression of genetic variability for GY is largely dependent on the level of N fertilization as evident from G (genotype) X N interaction in various experiments (Moll et al. 1987, Bertin and Gallais 2000).

#### 13.4.3.2 Quantitative Trait Loci for NUE

The improvement of crop yield has been possible through the indirect manipulation of QTLs that control the heritable variability of the traits and physiological mechanisms that determine biomass production and its partitioning. A critical analysis of how QTL-based approaches contribute to a better understanding of the genetic basis of crop performance has been explained elsewhere (Collins et al. 2008).

In temperate maize, Gallais and coworkers (Bertin and Gallais 2000, 2001, Gallais and Hirel 2004, Hirel et al. 2007) identified a set of QTLs for NUE and for GY and its components at high and low N levels. QTLs mapped in clusters and those identified under low N were generally a subset of those identified under high N, except for grain protein content, for which a higher number of QTLs were detected in low N. A number of genes that encode enzymes involved in N and C metabolism

were close to QTLs for vegetative development and for GY and its components (Gallais and Hirel 2004). These included genes for glutamine synthetase (GS; glutamine-ammonia ligase), sucrose-P synthase, sucrose synthase, and invertase ( $\beta$ -fructofuranosidase). The most notable outcomes of these studies were the colocation of a major GY QTL on chromosome 5 with the gene encoding cytosolic GS (*gln4* locus) and the correlation between the expression levels of the *gln4* alleles and the contributions of the respective QTL alleles at this locus. Other candidate genes encoding enzymes involved in N metabolism that collocated with NUE QTLs were the two GS genes (*gln1* and *gln2*) on chromosome 1 and the GS gene (*gln3*) on chromosome 4. Collectively, these results suggest that the increased productivity in maize genotypes under low N may be due to their ability to accumulate nitrate in the leaves during vegetative growth and to efficiently remobilize the stored nitrate during grain filling.

In tropical maize, QTLs for GY and secondary traits under varying N and water supply were identified by Ribaut et al. (2007). A mapping population previously developed for identifying QTLs under water-limited conditions was evaluated under varying N and water regimes. Two of the eight GY QTLs that were identified under low-N conditions were also detected under high-N conditions. Five QTLs were stable across the two low-N environments and five colocalized with QTLs identified for ASI (anthesis to silking interval) or for the number of ears per plant under low-N conditions. These results suggest that both ASI and the number of ears per plant can be selected simultaneously to improve the performance of maize under low N and drought stress (Ribaut et al. 2007). In wheat, a QTL meta-analysis and factorial regression were deployed to investigate QTL  $\times$  N interactions, revealing the influence of three major phenological trait loci, *Ppd-D1*, *Rht-B1*, and *B1*, on N-related QTLs (Laperche et al. 2007). Additionally, QTL clusters for GS activity on wheat chromosomes 2A and 4A coincided with the location of *GS* and *GSr* genes, respectively, and although QTL alleles for higher GS activity were associated with higher grain N, they showed little or no effects on GY components (Habash et al. 2007). QTLs for tolerance to low N have also been described in *Arabidopsis* (Loudet et al. 2003), rice (Lian et al. 2005), and barley (Mickelson et al. 2003).

### 13.4.3.3 Molecular Approaches for Improving NUE

From its inorganic origin to its biochemical destiny, N travels a long biological path that runs from soil to grains in the crop plants through numerous processes that operate in a coordinated way from uptake at root level to integration into the plant parts and grains after active N is released from applied N fertilizer in the rhizosphere. These processes are regulated at plant, cell, and molecular levels, and have been persistently explored to search avenues for improvement in NUE (Hirel et al. 2007, Pathak et al. 2008). The initial phase of molecular research for improved NUE in crop plants was based on the assumption that genes contributing to N uptake and N assimilation in plants are crucial. This has led to the accumulation of substantial knowledge on N uptake and assimilation mechanisms at the molecular level.

#### 13.4.3.3.1 Genes Associated with Regulation of N Uptake and Assimilation at Molecular Level

Plants take up and assimilate both nitrates and ammonium, with nitrate being the predominant form in most agricultural soils (Crawford and Glass 1998). Nitrate taken up by roots is then transported into cells via transporters from the NRT1 and NRT2 family of nitrate transporters (Forde 2000, Tsay et al. 2007). Once inside the cell, nitrate is reduced to nitrite by nitrate reductase (*NIA*), and then to ammonium by nitrite reductase (*NiR*). Ammonium is then assimilated into amino acids.

In addition to serving as a nutrient, nitrate also acts as a signal. When plants are first exposed to nitrate, genes in the nitrate assimilation pathway (*NRT*, *NIA*, *NiR*) are rapidly induced (Wang et al. 2007). Other genes, which are required for reprogramming carbon metabolism and providing chemical energy for reduction and assimilation, are also induced (Fritz et al. 2006). Transcriptome

analyses have shown that over 1500 genes are induced or repressed by nitrate within 20–180 min of treatment (Wang et al. 2007). Longer-term responses to nitrate include changes in root growth, development, and architecture, and in root-to-shoot ratios (Forde 2002, Walch-Liu et al. 2005, Walch-Liu et al. 2006). Enhanced Nicotinamide Adenine Dinucleotide Phosphate (NADP) (H) production due to the overexpression of *NADK2* (a chloroplastic Nicotinamide Adenine Dinucleotide (NAD) kinase) increased nitrogen assimilation. Glutamine and glutamate concentrations, as well as some other amino acids, were higher in the overexpressers. These results indicate that the overexpression of *NADK2* either directly or indirectly stimulates carbon (C) and N assimilation in *Arabidopsis* under restricted conditions (Takahashi et al. 2009).

*NRT1.1* mediates nitrate regulation of high-affinity nitrate uptake (Krouk et al. 2006). *NRT1.1* also controls the root colonization of nitrate-rich patches by a signaling pathway that may include *ANRI*, as both genes are expressed especially in root tips and *ANRI* derepression requires the *NRT1.1* function (Remans et al. 2006). A signaling role for *NRT1.1* is also supported by the finding that the nitrate reversal of glutamate inhibition of the primary root growth requires the *NRT1.1* function (Walch-Liu and Forde 2008, Forde and Walch-Liu 2009). The *NRT1.1* gene functions as a sensor in plants, which has been recently confirmed (Wang et al. 2009).

#### 13.4.3.3.2 Genes Associated with N Utilization

The regulatory mechanisms and genes responsible for N responses in plants have been investigated using genetics (Leydecker et al. 2000, Zhang and Forde 2000) and systems analysis (Gutierrez et al. 2005, Gutierrez et al. 2007). The ANR1 MADS (a DNA-binding protein conserved in plants, fungi, and animals) (Thomas 2001) box transcription factor, which controls lateral root branching in response to nitrate and is induced by N deprivation, was the first to be identified (Zhang and Forde 1998, Gan et al. 2005). A *Dof* (DNA binding with one finger) transcription factor was discovered that improves NUE at low N (Yanagisawa et al. 2004). More recent discoveries were the master clock control gene *CCA1*, which links organic N regulation and circadian rhythms (Gutierrez et al. 2008), and microRNA167, which mediates the cell-specific control of root development in response to N (Gifford et al. 2008). Most recently, a protein kinase, AtCIPK8, was identified that is needed for nitrate responses at high, but not at low, nitrate concentrations (Hu et al. 2009), and a DNA-binding protein, *AtNLP7*, which encodes the NIN-like protein 7 (NLP7), was found to function in the nitrate regulation of nitrate assimilation (Castaings et al. 2009). The *Arabidopsis* *NLP7* gene was recently shown to encode a nuclear-targeted protein that is needed for full nitrate induction of several nitrate-responsive genes (Castaings et al. 2009). *NLP7* mutants have altered root growth (longer primary roots and more lateral roots) typical of N-starved plants and are more resistant to water stress. However, this accumulated knowledge on the molecular aspects of N uptake is yet to be exploited for enhancing NUE in crop plants.

The most success in terms of increasing NUE through genetic modification has been through the overexpression in the roots of alanine aminotransferase (*AlaAT*), a downstream process in N assimilation (Good et al. 2007). In transgenic canola, yields were higher at low N associated with higher influx of N. In this material root alanine was increased and shoot glutamine decreased. Transgenic *Brassica napus* plants overexpressing a barley *AlaAT* cDNA, driven by a *Brassica* root-specific promoter (*btg26*), showed improved NUE. Compared with wild-type *Brassica*, transgenic plants showed increased biomass and seed yield in both the laboratory and field under low-N conditions, whereas no differences were observed under high-N conditions. These changes resulted in a 40% decrease in the amount of applied N fertilizer required under field conditions to achieve yields equivalent to those of wild-type plants (Good et al. 2007). A similar strategy was used for improving NUE in rice (Shrawat et al. 2008). Nipponbare, a model rice plant, was genetically engineered by introducing a barley *AlaAT* cDNA driven by a rice tissue-specific promoter (*OsAnt1*). This modification increased the biomass and GY significantly in comparison with control plants when plants were well supplied with N. Compared with controls, transgenic rice plants also demonstrated significant changes in key metabolites and total N content, indicating increased N UPE.

# 13.5 STRATEGIES AND OPPORTUNITIES FOR GENETIC IMPROVEMENT OF NUE

## 13.5.1 TARGETS FOR NUE IMPROVEMENT

### 13.5.1.1 Target Environments for NUE Improvement

The N response of a crop plant is highly influenced by the type of agro-eco environment, as plant growth and N loss mechanisms are largely determined by soil and climatic factors, as described in Section 13.4. This is also evident from an estimate of NUE across the regions, as presented in Figure 13.1. Hence, there should be a clear idea about the target environment for a particular crop. For the sake of simplicity, the target agro-eco environments for crop plants may be grouped into high-input environments and low-input environments. The high-input environments need a crop with high NUE to reduce the amount of fertilizer applied and enhance profit for farmers through a substantial reduction in the adverse impact of excess N on the environment. On the other hand, low-input environments need crops with NUE that can enable plants to take up and utilize limited N available for growth, development, and yield.

### 13.5.1.2 Realistic Target for Improved NUE and Its Possible Impact

There should be a realistic target for NUE for a particular crop for a particular agro-eco environment. For example, Brazil consumes about 150,000 tons of N fertilizers for rice cultivation, and the total N used to cultivate rice alone across the world is more than 17.4Mt, which amounts to 15%–17% of the total N use in agriculture (Heffer 2009). An optimistic research target of about 30% reductions in the applied N fertilizer without compromising the crop productivity can substantially benefit rice cultivation in the tropics. This is possible if NUE is enhanced from about 40%–57% (Figure 13.2).

### 13.5.1.3 Defined N-Threshold for Estimating Genetic Difference among Varieties

Crop plants, in general, differ in their ability to recover fertilizer N, and this is influenced by factors such as soil type and climatic conditions. Before initiating the experiments to determine genetic variability among the genotypes for NUE, it is necessary to determine the optimum level of fertilizer at which the plant yield is at its maximum for a given environment along with the recommended agronomic practices. The computation of fertilizer recovery should necessarily consider the native

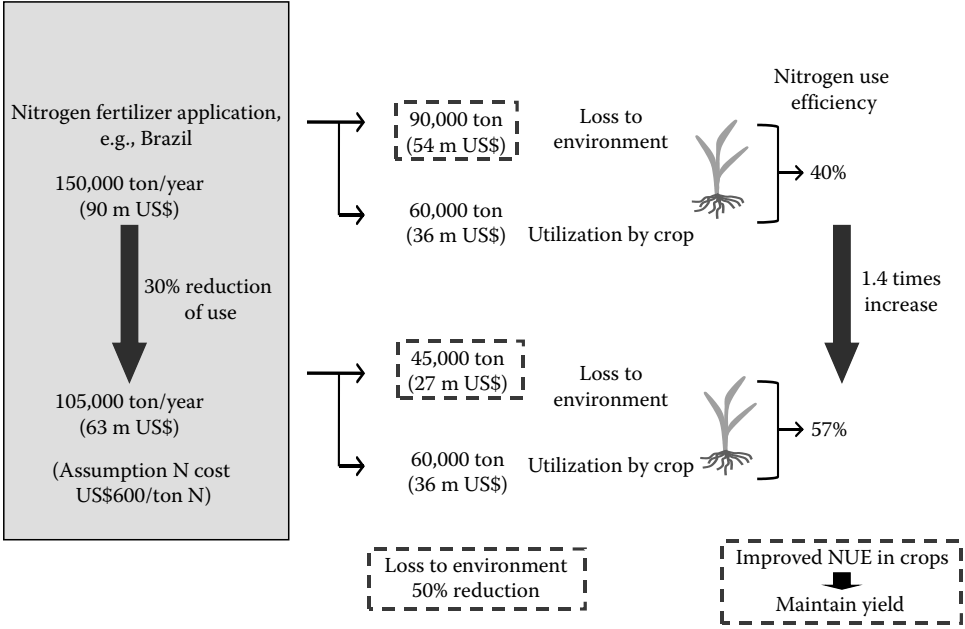

FIGURE 13.1 NUE of cereals across different regions. (From Doberman, 2006.)

**FIGURE 13.2** A hypothetical model showing the expected impacts of improvement in NUE in crop plants such as rice.

**FIGURE 13.3** A hypothetical N response curve and optimum N level for determining genetic variability in NUE.

N availability and its uptake by a check variety. For example, in Figure 13.3, it is clear that the benefits of additional fertilizer diminish beyond an N rate of 100 kg ha<sup>-1</sup>. So, the target for genetic improvement may be to develop a genotype that can produce more GY in response to the optimum N level, that is, 100 kg ha<sup>-1</sup> or the same level of GY at 50%–70% of the optimum fertilizer. This approach may be preceded by the use of the available crop model to estimate the optimum level of N to get the maximum yield under a particular environment. The validation of enhanced NUE through a molecular approach should consider the whole plant growth and development as well as GY in a given environment.

### 13.5.2 IMPROVING NUE COMPONENTS

#### 13.5.2.1 Improving N Uptake by Plant

In addition to the regulation of N supply by modern methods and conventional agronomic practices, there are also opportunities to genetically improve the N uptake by plant. This may be accomplished through an improvement in plant architecture in general and, specifically, the root (Garnett et al. 2009). Some of the suggested options to improve NUE through an improved root system were increased root-to-shoot ratio, high root vigor, N-induced root proliferation, root length density, root hairs, root exudates, microbial symbiosis, and root N metabolism. The utility of these traits in isolation or in combination is largely determined by the target crop environment.

As opined by Garnett et al. (2009), very little is known about how the various N transporters contribute to the net N uptake by crops in field situations or how this changes over the life of the crop. Furthermore, the mechanisms regulating the distribution of  $\text{NO}_3^-$  and/or  $\text{NH}_4^+$  from the root to the shoot remain poorly understood. Research in these areas will make it easier to focus on targets for improving NUE through increasing N UPE.

We now have evidence that all high-affinity  $\text{NO}_3^-$  transport systems appear to be induced by the presence of  $\text{NO}_3^-$ , and then down-regulated by the accumulation of endogenous N levels. This type of regulation exists even for an  $\text{NH}_4^+$  transporter. It is visualized that transcriptional and post-transcriptional regulation of events that follow the N uptake are essential to get benefit from the overexpression of high-affinity  $\text{NO}_3^-$  transporters, particularly at stages of plant development when both soil and plant N levels are abundant. This approach was successfully demonstrated by the overexpression of the *Dof1* transcription factor, which in *Arabidopsis* avoided the transport regulation processes and increased the N content of the plants by 30% (Yanagisawa et al. 2004).

#### 13.5.2.2 Improvement in N Utilization

Two possibilities related to the improvement of N distribution among plant organs have been suggested to increase crop productivity (Dreccer et al. 1998). The first one is to select cultivars with a greater capacity to store N in non-photosynthetic organs, such as internodes that allow the translocation of a larger amount of N to grains without reducing plant photosynthetic capacity (Martre et al. 2007). This is one trait associated with the “stay green” behavior, resulting in delayed leaf senescence and improved GY (Borrell et al. 2001). However, one needs to be careful as the gene for high grain protein content could accelerate senescence in leaves (Uauy et al. 2006). The second possibility is to improve the vertical distribution of N among leaves. Theoretical studies have suggested that canopy photosynthesis would be maximized if N is preferentially allocated to the more illuminated leaves (Field 1983). A vertical N distribution that follows the light gradient would allow higher photosynthesis compared with that expected from a uniform N distribution (Mooney and Gulmon 1979). The role of N dynamics on canopy photosynthesis and crop productivity will likely become even more important in the future because of climate change and the associated increase of atmospheric  $\text{CO}_2$  concentration (Kim et al. 2001, Anten et al. 2004).

### 13.5.3 MINIMIZING LOSS OF APPLIED N

Loss of applied N in the soil can be minimized through exploiting genetic variability in biological nitrification inhibition (BNI) by root exudates of a crop plant (Subbarao et al. 2006). Recently, an effective BNI has been discovered in the root exudates of the tropical forage grass *Brachiaria humidicola* (Rendle) Schweick (Subbarao et al. 2009). Named “brachialactone,” this inhibitor is a cyclic diterpene with a unique 5-8-5-membered ring system and a  $\gamma$ -lactone ring. It contributed 60%–90% of the inhibitory activity of exudates released from the roots of this tropical grass. Unlike nitrapyrin (a synthetic nitrification inhibitor), which affects only the ammonia monooxygenase (AMO) pathway, brachialactone appears to block both AMO and hydroxylamine oxidoreductase enzymatic pathways in *Nitrosomonas*. The release of this inhibitor is a regulated plant

function, triggered and sustained by the availability of ammonium ( $\text{NH}_4^+$ ) in the root environment. Brachialactone release is restricted to those roots that are directly exposed to  $\text{NH}_4^+$ . Within 3 years of establishment, *Brachiaria* pastures have suppressed soil nitrifier populations (determined as *amoA* genes; ammonia-oxidizing bacteria and ammonia-oxidizing archaea), along with nitrification and nitrous oxide emissions. These findings provided direct evidence for the existence and active regulation of a nitrification inhibitor (or inhibitors) release from tropical pasture root systems. Exploiting the BNI function could become a powerful strategy toward the development of low-nitrifying agronomic systems, benefiting both agriculture and the environment. The BNI activity of root exudates has been reported in *Brachiaria* and rice (Subbarao et al. 2007, 2009, CIAT 2008). However, long-term field experiments are needed to assess trade-offs between crop productivity and BNI, since the accumulation of compounds such as phenols in soil due to continuous rice cultivation may affect late season crop growth (Olk 2009).

#### 13.5.4 PHENOTYPING THE GENETIC RESOURCES AND MAPPING POPULATION

As described in Section 13.4.3.2, numerous attempts have been made to identify QTLs and genes associated with NUE; however, to the best of our knowledge, none of the discovered QTLs and genes have been applied successfully for a marker-aided selection for NUE in any of the crop in the public sector. This could be largely attributed to the complexity of NUE as a trait and the associated G X E interactions. It points out the need for gene or marker discovery based on precise high-throughput phenotyping for NUE under field and controlled environment.

A forward genetic approach that involves phenotyping followed by genotyping is the conventional way of associating a phenotype with the relevant gene. Attempts have been made earlier to screen germplasm for NUE; however, there is a need for scaling up this activity by utilizing recent advances in molecular techniques and phenomics. Reverse genetics that involves genotyping followed by phenotyping has recently become popular because of the access to DNA sequence data and information on gene function placed in public domain. This approach largely depends on the size of the target plant population screened as well as the accuracy of phenotyping. Hence, high-throughput screening is crucial to boost the reverse genetic approach for the discovery of genes that are associated with NUE. These techniques of phenomics can also accelerate phenotyping of diverse sets of genetic material that comprise germplasm collections; mutant libraries; mapping populations, such as recombinant inbred lines, advanced backcross lines, doubled haploid lines, and chromosome segment substitution lines (CSSLs); as well as minicore sets identified from germplasm collections. Phenomic techniques should not be restricted to control environments, but should also be adopted to screen a large number of plants under real field conditions. Appropriate criteria for designing phenotyping protocols in controlled and field environments are essential for improving NUE in cropping systems.

#### 13.6 FUTURE PERSPECTIVES

The major challenges to improve NUE include optimization of N supply and demand, maximization of crop N uptake, maximization of crop N assimilation, minimization of N losses, improvement in crop productivity, and interaction with other factors such as soil moisture. As shown in Table 13.2, there are great opportunities to address these challenges through agronomic, breeding, and molecular approaches. An efficient root system, BNI, and nitrate transporters may contribute to improved N UPE (Table 13.3). On the other hand, genetic manipulations leading to efficient C:N metabolism, enhanced efficiency of enzymes associated with N metabolism, and improved biomass partitioning to grain can contribute to improved NUE (Figure 13.4).

Genes and QTLs have been identified for NUE, but need to be validated in field conditions under different agro-eco environments. The significance of transgenes contributing to NUE has been demonstrated in the laboratories with model plants, such as *Arabidopsis* and *Nippombare*

**TABLE 13.2**  
**Strategies and Opportunities for Improving NUE in Crop Plants**

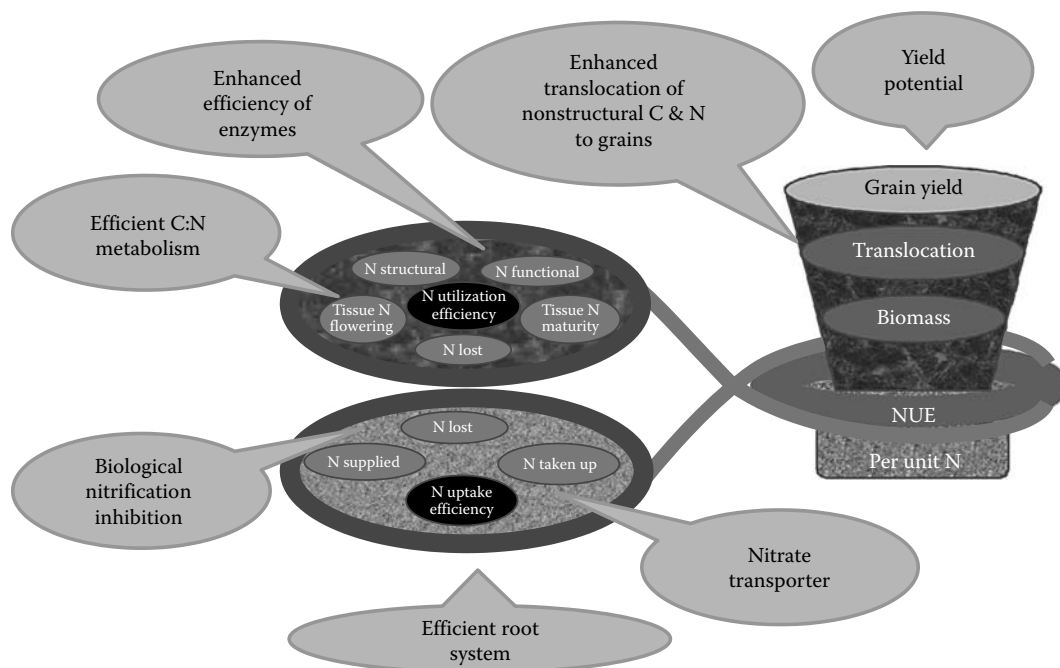

| Challenges                                   | Traits to be Improved                  | Agronomic Intervention                                                                                                                             | Genetic Improvement                   | Molecular Intervention                                                                                                                   |
|----------------------------------------------|----------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------|---------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------|
| Optimization of N supply                     | N UPE                                  | Split application; cover crop fertilization (Reiter et al. 2008); crop residue management (Reiter et al. 2008); precision agriculture (Table 13.3) | —                                     | —                                                                                                                                        |

| Minimization of N losses                     | N UPE, N UTE/ physiological efficiency | Slow-releasing fertilizers (Golden et al. 2009)                                                                                                    | Exploiting genetic variability in BNI | Genes associated with root architecture                                                                                                  |
| Maximization of crop N assimilation          | N UTE/ physiological efficiency        | —                                                                                                                                                  | —                                     | Manipulation of enzymes associated with N assimilation                                                                                   |
| Improvement in crop productivity             | Biomass partitioning                   | Recommended package of practices                                                                                                                   | Increased yield potential             | —                                                                                                                                        |
| Interaction with other factors such as water | Stacking traits of NUE + WUE+ yield    | Irrigation and soil management                                                                                                                     | Resistance to abiotic stress          | Manipulation of stress tolerance genes; gene stacking                                                                                    |

**TABLE 13.3**  
**Recent Agronomic Approaches for N Management**

| Technologies                                                                         | Description                                                                                                                                                                                                                                                  | References          |
|--------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---------------------|
| Sensor-based N application                                                           | Use of plant sensors–based diagnostic information for nitrogen recommendations                                                                                                                                                                               | Marek et al. (2009) |
| Automated calibration stamp technology for improved in-season nitrogen fertilization | Calibration stamps applied at preplant or soon after planting can assist in providing visual interpretation of N mineralization + atmospheric N deposition from planting to the time midseason N is applied, and improved determination of top dress N rates | Raun et al. (2005)  |
| In-season optical sensing                                                            | The optical sensor–based N management strategy is relatively easy to use, has better potential to improve NUE and economic returns, and reduces residual soil N content and apparent N loss                                                                  | Li et al. (2009)    |

(a rice variety) and also Brassica. In a review of the application of genomics to biotechnology traits, Gutterson and Zhang (2004) outlined a typical development process for an agricultural biotechnology product, which can take up to 12 years or more from gene discovery to a commercial product. The major challenge after discovering the lead in model plants, like Arabidopsis or a rice genotype such as Nipponbare, is its utility in the background of the commercial crop variety that is well adapted to the target environment. This technology needs to be evaluated under different environments with crop plants that are adapted to target environments with an appropriate phenotyping protocol.

**FIGURE 13.4** NUE components and possible approaches for improvement.

In addition to the conventional approach, advances in hyperspectral image-based phenomics are expected to accelerate plant phenotyping to a great extent (Furbank 2009). At present, many of these technologies are restricted to controlled environments, and are likely to be extended to field in the near future. This will enhance the capacity to screen genetic resources for new genes that are associated with NUE, and also will contribute to the validation of the technologies that are already applied in controlled environments.

## ACKNOWLEDGMENT

The preparation of this chapter was partially supported by the restricted funding to CIAT from the Ministry of Foreign Affairs (MOFA) of the Government of Japan.

## 14.1 INTRODUCTION

Chloroplasts are crucial for plant cell metabolism since they perform a unique and complex process named photosynthesis. This process is also vital for aerobic and heterotrophic life on Earth, because it provides the carbohydrates that are sustaining every food chain. The light reactions of photosynthesis use very abundant resources on Earth, water, and sunlight, to produce oxygen and provide chemical energy (ATP) and reducing power (NADPH). These two compounds drive the dark reactions of photosynthesis, namely, CO<sub>2</sub> fixation into carbohydrates, but also the synthesis of many other essential components, including fatty acids, amino acids, and nucleic acids, all taking place

in the chloroplast stroma. The photosynthetic apparatus consists of four major complexes involved in the light reactions, namely, the water-oxidizing photosystem II (PSII), cytochrome *b<sub>6</sub>f* (cyt *b<sub>6</sub>f*), photosystem I (PSI), and the H<sup>+</sup>-translocating ATP synthase (CF<sub>0</sub>F<sub>1</sub>), all four located in the thylakoid membrane of cyanobacteria, algae, and higher plants. The first three photosynthetic complexes are involved in sunlight absorption, electron extraction, and transfer from water to NADP<sup>+</sup>, whereas the fourth complex uses the H<sup>+</sup> gradient created across the thylakoid membrane during electron transfer to power ATP synthesis.

Plants utilize sunlight to drive photosynthetic energy conversion, but this event may also cause inactivation of the photosynthetic apparatus (photoinhibition), primarily of the PSII complex, affecting the plant daily productivity (Kok, 1956; Jones and Kok, 1966a,b; Powles, 1984; Mattoo et al., 1989). The extent of photoinhibition is the result of a dynamic balance between photodamage and repair of PSII (Ohad et al., 1984; Aro et al., 1993; Aro et al., 2005). Therefore, photoinhibition occurs only under conditions when the rate of photodamage exceeds the rate of repair. To avoid photoinhibition, plants use photoprotective mechanisms (see Chapter 16) to either suppress the damage or to facilitate the repair of damaged PSII.

The repair of damaged photosynthetic machinery must be rigorously regulated, and crucial for this is an array of “auxiliary” proteins, such as kinases, phosphatases, proteases, stress-induced and heat-shock proteins, as well as solute and metabolite transporters. As compared to the available knowledge concerning photosynthetic machinery, there is still a lot to be done in the field of transport proteins to understand their importance for the photosynthetic process itself but also in the functioning of other plastid types. This chapter focuses on chloroplast transporters, which are specialized integral membrane proteins localized in the outer envelope, inner envelope, or in the thylakoid membrane. Their function is to exchange solutes and metabolites between the chloroplast stroma and cytosol or between the stroma and thylakoid lumenal space. The majority of the substrates are anions, e.g., adenine nucleotides, phosphate, sulfate, but some are cations, e.g., H<sup>+</sup>, Na<sup>+</sup>, Ca<sup>2+</sup>, and Cu<sup>2+</sup>. All chloroplast transporters are nuclear-encoded proteins, and have to be imported and inserted into the envelope or the thylakoid membrane. Chloroplast transporters, described in this chapter, play an important role in biogenesis, optimal function, acclimation, and repair of the photosynthetic apparatus to ensure its efficiency under ever-changing and even stressful environmental conditions.

## 14.2 PHOTOSYNTHESIS, PHOTOACCLIMATION, AND PHOTOINHIBITION

Many structural and functional advances have been made during the past 10 years when it comes to the photosynthetic apparatus (Nelson and Ben-Shem, 2004; Merchant and Sawaya, 2005). A view of this amazing machinery at atomic resolution is a prerequisite for understanding the mechanism of its function and regulation. The crystal structures of the four major photosynthetic complexes have revealed their protein composition and interactions, and the arrangement of cofactors. In addition, they allow very refined models of the key features of their function, which will be the task for biophysicists and molecular biologists to validate.

PSII or water–plastoquinone oxidoreductase is the first complex in the photosynthetic electron transfer pathway. It is a membrane protein complex composed of over 25 different subunits and many functional cofactors, including chlorophylls, carotenoids, quinones, lipids, Cl<sup>−</sup>, and metal ions (Fe<sup>2+</sup>, Mn<sup>2+</sup>, Ca<sup>2+</sup>), as revealed by several crystal structures of cyanobacterial PSII, published at increasing resolution (Kamiya and Shen, 2003; Ferreira et al., 2004; Guskov et al., 2009). Most of the active redox cofactors involved in the PSII electron transport are bound on the innermost subunit, namely, the reaction center D1 protein. The available crystal structures revealed that, similar to many other membrane protein complexes, the functional unit of PSII *in vivo* is a dimer, although recent reports propose instead the monomeric form (Takahashi et al., 2009; Watanabe et al., 2009). This finding would challenge the current models of PSII complex during light-induced damage–repair cycle, where the monomeric form has so far been considered only an intermediate form.

A multilevel network of adaptation/acclimation strategies exists to help plants to cope with fluctuations of intensity in the light environment, ensuring high levels of plant survival and productivity (Ruban, 2009). These levels can be divided as follows: organism level (slow, e.g., leaf orientation), cellular level (fast, e.g., chloroplast orientation), and molecular level (most profound, long-term: change in chlorophyll and chlorophyll-binding protein content; short-term: changes in the light-harvesting efficiency by state transitions, and thermal energy dissipation). A central role is played by the light-harvesting antenna complex (LHCII), which collects and (then) delivers the sunlight to the reaction center of PSII. The amount of delivered light is crucial because too much light triggers photoinhibition. Therefore, modulation of light harvesting has to be fine-tuned. Thermal energy dissipation is the major component of non-photochemical quenching (NPQ), and is triggered by the acidification of the thylakoid lumenal space (Oxborough and Horton, 1988). NPQ is localized within the LHCII antenna and not the PSII reaction center, and is dependent upon the presence of exclusively LHCII-bound xanthophylls, lutein, and zeaxanthin (Ruban and Horton, 1994; Niyogi et al., 2001). NPQ also requires the presence of the PsbS protein and the activity of the violaxanthin de-epoxidase cycle (Yamamoto et al., 1962; Li et al., 2002; see Chapter 16).

A sustained exposure to excess radiance will, however, lead inevitably to photoinhibition, and a decline in photosynthetic efficiency and productivity. The reaction center of PSII is the most susceptible to the photodamage due to the very strong oxidation potential of its reaction center chlorophyll (P680, 1.17 V) needed to oxidize water. If there are problems on the donor side, P680<sup>+</sup> lifetime will increase; this will oxidize pigments and amino acids, causing their degradation, and the subsequent degradation of the D1 protein. If the acceptor side is less efficient, this will lead to the formation of P680 triplet that will interact with oxygen and form singlet oxygen, which, in turn, will oxidize amino acids of the D1 protein, and lead to its subsequent degradation (Vass et al., 1992). Later on, using EPR technique, it has been demonstrated that distinct reactive oxygen species (ROS) are formed during the two types of photoinhibition, namely, hydroxyl radicals during the donor-side type and singlet oxygen during the acceptor-side type (Hideg et al., 1994). Plants survive photoinhibition through several mechanisms; among them, the PSII repair cycle includes D1 degradation, its *de novo* synthesis, and its reintegration into the reaction center. In a recent scheme, different from the “classical” one, Murata et al. (2007) proposes that the photodamage occurs primarily at the oxygen-evolving complex of PSII, and that high levels of intracellular ROS, such as H<sub>2</sub>O<sub>2</sub> and singlet oxygen, inhibit repair of PSII by suppressing *de novo* synthesis of the D1 protein.

Various types of environmental stresses, such as cold, heat, salt, and oxidative stress enhance the extent of photoinhibition. Originally, it has been assumed that this is a result of an enhanced damage to PSII, but most recent results show that the above-mentioned environmental factors increase the imbalance between photodamage and repair, since they produce ROS, which suppress D1 protein synthesis at the translational step (Takahashi and Murata, 2008). Another possibility proposed by the same authors is that the acceleration of photodamage is the result of an inhibition of photosynthetic CO<sub>2</sub> fixation by the above stress factors, which can regulate the generation of ROS.

In spite of considerable effort, our knowledge about the mechanism of D1 protein and PSII turnover during high light stress is still relatively fragmentary. Moreover, we know very little about the biogenesis and assembly of the photosynthetic apparatus under optimal growth conditions. It is known that the thylakoid membrane in higher plants has a characteristic structure since it is organized in appressed (grana) and non-appressed (stroma) thylakoids with distinct composition: grana thylakoids contain mainly PSII, while stroma lamellae are highly enriched in PSI and ATP synthase (Anderson and Andersson, 1982). Therefore, the complexes must acquire their correct location for assembly into functional units. The mechanisms involved in lateral trafficking of newly synthesized proteins into and from grana lamellae are not known. All polypeptides appear to integrate first into the stroma lamellae and perhaps also into the exposed grana regions, and migrate subsequently either as individual polypeptides or in assembled complexes to their final destination.

### 14.3 ARABIDOPSIS AS A MODEL PLANT IN PHOTOSYNTHESIS RESEARCH

The first published sequenced genome of a plant was that of *Arabidopsis thaliana*, almost 10 years ago (Arabidopsis Genome Initiative, 2000), and is used since then as a model organism in plant genomics research. After that, the genome sequences of two plants of economic importance, namely, rice (*Oryza sativa*) and poplar (*Populus trichocarpa*), and two model plants, *Medicago* (*Medicago truncatula*) and the moss (*Physcomitrella patens*) have also become available (International Rice Genome Sequencing Project, 2005; Tuskan et al., 2006; Retzel et al., 2007; Rensing et al., 2008). In addition, projects for sequencing many other plant genomes are in progress, according to the National Center for Biotechnology Information (NCBI) Entrez Genome projects website (<http://www.ncbi.nlm.nih.gov/>). These are either model plants or species of economic importance. References to organism-specific databases for the ongoing genome sequencing projects are provided in Table 14.1.

Among the sequenced plant genomes, *Arabidopsis* has the smallest plant genome (125 Mb) and a number of over 28,500 predicted genes (Arabidopsis Genome Initiative, 2000). For comparison, rice has around 41,000 genes, poplar more than 45,000 genes, and *Medicago* more than 40,000 genes (Sterck et al., 2007). Despite the rather small range of gene numbers, a large increase in the plant genome size has occurred during evolution and attributed to many duplication events. When the sequencing of *Arabidopsis* started, it had not been expected that this model plant with such a small genome could be an ancient polyploid. It has turned out that 60% of the genome is duplicated, and that

Note: The number of publications were taken from PubMed (<http://www.ncbi.nlm.nih.gov/sites/entrez>) (2009-11-11).

this is the result of three steps of duplication during 150–200 million years (Simillion et al., 2002). Another reason for the large genome size of land plants could be their unique lifestyle, since they are sessile, and thus need genes and strategies to acclimate to abiotic stress and to defend biotic stress.

Unraveling the molecular details of the photosynthetic reactions has been a central topic of research in biochemistry and biophysics. Among higher plants, spinach has been the model for biophysics, and especially for biochemistry of photosynthesis. However, the spinach genome has not been sequenced, and there are no plans to do so (Table 14.1). As in present life sciences in general, identifying sequences and mutating genes encoding specific proteins have revealed a vast amount of new knowledge, which could not be obtained using conventional biochemistry. Determination of the complete genome sequence of model photosynthetic organisms, such as the cyanobacterium *Synechocystis* sp. PCC 6803, the green algae *Chlamydomonas reinhardtii*, and the higher plant *A. thaliana*, has been a significant development.

The genome of *Synechocystis* sp. PCC 6803 has been sequenced by Kaneko et al. (2006). It is a prokaryotic oxygenic photosynthetic organism, used as a model for photosynthesis research because the reaction centers (RCs) are highly similar to those in plants. Its major limitation is that the light-harvesting system and the oxygen-evolving complex in *Synechocystis* are rather different from those in plants, and that the *cyt b<sub>6</sub>f* complex is part of both respiratory and photosynthetic electron transport chains. *C. reinhardtii* genome has been sequenced by Merchant et al. (2007). It has been used as a model for photosynthesis research for more than 50 years, and some of the reasons are listed below: ability to grow heterotrophically, ability to synthesize chlorophyll in darkness, and easiness to perform chloroplast transformation (Dent et al., 2001). *Arabidopsis* has become a model organism in plant genomics and also in photosynthesis research due to several factors: easy to cultivate, short life cycle, self-progeny, publicly available genome sequence, predicted sequence information, gene expression data, and collections of DNA and seeds (The Arabidopsis Information Resource Web site and associated links; <http://www.arabidopsis.org/>). The number of publications on photosynthesis found at NCBI Web site since 1950 is similar in *Arabidopsis* and spinach (Table 14.1). However, much more has been published using *Arabidopsis* as plant material since 2000, the year of its genome sequencing. Therefore, in the last decade, molecular genetics has provided a new and powerful tool in this area of research.

#### 14.4 PLANT MEMBRANE TRANSPORTERS: CLASSIFICATION AND STRATEGIES FOR IDENTIFICATION

According to the Transport Classification (T.C.) system available at the TCDB database (<http://www.tcdb.org/>), the membrane transport proteins found in biological membranes have been divided into three categories: channels/porins, secondary transporters, and primary transporters (pumps). The channels (T.C. #1) are non-energy consuming, since they transport down the gradient and are the fastest ( $10^7$ – $10^8$  molecules/s); the secondary transporters (T.C. #2) use the gradient of cotransported molecules for transport ( $10^2$ – $10^4$  molecules/s); and the pumps (T.C. #3) consume energy (mainly ATP) for transport, and are the slowest ( $1$ – $10^3$  molecules/s). The most common subtypes of these three categories are illustrated in Figure 14.1. The two main types of secondary transporters are antiporters (counter-transport) and symporters (cotransport). Symporters use the downhill movement of one solute species from high to low concentration to move another molecule uphill from low concentration to high concentration, i.e., against its electrochemical gradient. There is a third type of secondary transporters designated uniport, when a single species is transported either by facilitated diffusion or in a membrane-potential-dependent process, if the solute is charged. There are four types of ATP-utilizing pumps in biological membranes, namely, ATP-binding cassette (ABC) transporters,  $H^+$ -translocating F-ATPases, vacuolar V-ATPases, and metal ion-transporting P-ATPases. Pumps transport either molecules in specific directions independent of the environmental situation, or ions to build a concentration gradient between the outside and the inside of the membrane (i.e., active transport). Plants also contain transporters that so far could not be assigned to a certain category (T.C. #9).

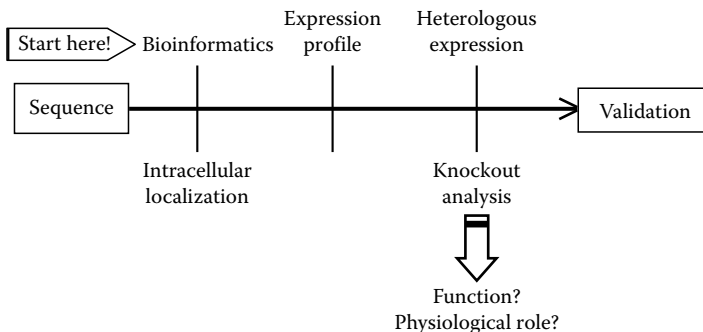

**FIGURE 14.1** Schematic illustration of the most common types of transporters in biological membranes.

Except for TCDB, there are several other excellent databases for membrane transporters, namely, TransportDB for genomic comparison of membrane transport systems (<http://www.membranetransport.org/>), PlantsT for functional genomics of plant transporters (<http://plantst.genomics.purdue.edu/>), and ARAMEMNON for sequence analysis of plant membrane proteins (<http://aramemnon.botanik.uni-koeln.de/>). Interestingly, the total number of membrane transporters in plants is 1.2 to 2.0-fold higher than in animals, and explained on the basis of their immobility (Nagata et al., 2008). The same report presents bioinformatics data revealing a smaller number of ion channels in plants than in animals, and at the same time a larger number of pumps and secondary transporters. The latter observation is explained by the fact that plants have chloroplast synthesizing ATP during photosynthesis, which is used by pumps to drive the transport of molecules, which in turn, act as the driving force of secondary transporters.

The major structural features of membrane transporters are a hydrophobic structure, a pore-forming sequence, and molecule-binding sites. Based on these specific features, homologues of known membrane transporters can be identified using bioinformatics. Following the sequencing of the *Arabidopsis* genome (Arabidopsis Genome Initiative, 2000), bioinformatics analyses have estimated that 5%–10% of the nuclear-encoded proteins represent membrane transporters (Weber et al., 2005). Most recently, Nagata et al. (2008) reported that *Arabidopsis* has around 1000 transporters, which represent 4.5% of its genome, and include 13% ion channels, 67% secondary transporters, and 18% ATP-dependent pumps.

As compared to the knowledge we have concerning the photosynthetic machinery, there is still a lot to be done in the field of chloroplast transport proteins. First, there is need to identify them, and then to thoroughly characterize their function and physiological role. Proteomics has been a very successful approach in identifying a tremendous number of chloroplast proteins (Schröder and Kieselbach, 2003; Rolland et al., 2003; van Wijk, 2004). The identification using large-scale mass-spectrometry-based proteomics is hampered by the fact that, as regulatory proteins, they are present in amounts predicted to be  $10^7$ – $10^{14}$  fold lower than those for the photosynthetic proteins. The

**FIGURE 14.2** Schematic representation of *in silico* and experimental approaches used in functional genomics.

alternative is to mine the available sequence information of model plants such as *Arabidopsis*, and use a functional genomics approach (Figure 14.2; Barbier-Brygoo et al., 2001). This includes prediction of intracellular location and function using sequence-based bioinformatics tools, localization studies using green fluorescent protein-constructs and fluorescence microscopy, expression studies using quantitative RT-PCR, functional studies using heterologous expression and activity assays, and phenotypic analyses of knockout mutants.

14.5 CHLOROPLAST TRANSPORTERS

Chloroplast membrane proteins belong to one of the following three compartments: outer envelope, inner envelope, or thylakoid membrane. These chloroplast membranes are distinct subcellular compartments in several aspects. The outer chloroplast envelope membrane has been thought for a long time to be freely permeable to solutes, while the inner envelope and the thylakoid membrane function as selective barriers. However, several transporters (e.g., porins) have been most recently found in the outer envelope membrane (Duy et al., 2007a). Chloroplast transporters belonging to channels, secondary transporters, pumps, and so far unclassified transporters are reviewed in this chapter. Tables 14.2 through 14.4 include accession numbers for *Arabidopsis* members, together with their experimentally validated location, substrate specificity, and physiological role. Figure 14.3 provides an overview of the transporters so far identified and characterized in the chloroplast thylakoid membrane of *Arabidopsis*.

*Note:* The classification is according to the Transport Classification Database (<http://www.tcdb.org/>). The accession numbers in *Arabidopsis* (Arabidopsis gene index, AGI) is indicated. n.d., not determined. The source of these data is given in the text describing each chloroplast member.

### 14.5.1 CHANNELS/PORINS

Channels/porins (T.C. #1) catalyze facilitated diffusion by passage through a transmembrane aqueous pore or channel without evidence for a carrier-mediated mechanism. Channels are the fastest at transporting molecules down their concentration gradient without consuming energy. There are five different types, which include  $\alpha$ -type channels (T.C. #1.A) and  $\beta$ -barrel porins (T.C. #1.B). The  $\alpha$ -channel proteins usually consist largely of  $\alpha$ -helical spanners, although  $\beta$ -strands may be

*Note:* The classification is according to the Transport Classification Database (<http://www.tcdb.org/>). The accession numbers in Arabidopsis (Arabidopsis gene index, AGI) is indicated. n.d., not determined. The source of these data is given in the text describing each chloroplast member.

**FIGURE 14.3** Overview of transporters identified from the thylakoid membrane of *Arabidopsis thaliana*. Chloroplasts are structurally organized in three membrane compartments (outer envelope, inner envelope, and thylakoid membrane), and two soluble compartments (stroma and thylakoid lumen). The diagram shows the following transporters that have been localized to the thylakoid membrane and functionally characterized: the  $H^+$ -translocating ATPase ( $CF_0F_1$ ), the  $Cu^{2+}$ -transporting P-type ATPase (PAA2), the thylakoid ATP/ADP carrier (TAAC), the  $Na^+$ -dependent  $P_i$  transporter (ANTR1), and the chloride channel CLCe.

present and may even contribute to the channel. They are ubiquitously found in the membranes of all types of organisms from bacteria to higher eukaryotes. The transmembrane portions of porins consist exclusively of  $\beta$ -strands, which form a  $\beta$ -barrel. These proteins are found in the outer membranes of Gram-negative bacteria, mitochondria, and plastids. Chloroplast channels and porins are described below and summarized in Table 14.2.

Ion channels belong to the  $\alpha$ -type and regulate the flow of ions across the membrane in all cells. They conduct a specific species of ion, such as  $Na^+$  or  $K^+$ , and convey them through water-filled pores nearly as quickly as the ions move through free fluid. In some ion channels, passage through the pore is governed by a “gate,” which may be opened or closed by chemical or electrical signals, temperature, or mechanical force, depending on the channel type. Ion channels may be classified by the nature of their gating (i.e., what opens and closes the channels), the species of ions passing through those gates, and the number of gates (pores). Voltage-gated ion channels (VIC) activate/inactivate depending on the voltage gradient across the plasma membrane, while ligand-gated ion channels activate/inactivate depending on binding of ligands to the channel.

#### 14.5.1.1 Voltage-Gated Ion Channels

VIC (T.C. #1.A) is probably the largest subfamily of channels. The functionally characterized members are specific for  $K^+$ ,  $Na^+$ , and  $Ca^{2+}$  ions. Proteins of the VIC family are ion-selective channel proteins found in a wide range of bacteria, archaea, eukaryotes, and viruses. There are five members of this family predicted as chloroplast proteins (Weber et al., 2005). However, none of them has been so far characterized or identified in chloroplasts.

During photosynthetic light reactions, an electrochemical  $H^+$  gradient is generated between the chloroplast stroma and the thylakoid lumen, which is primarily used by the  $CF_0F_1$  to drive ATP synthesis. Evidence has been provided for the operation of ion channels in series with the electron

transfer chain (Cruz et al., 2001), which would electrically balance light-driven  $H^+$  transport. It is, indeed, well established by now that mainly  $K^+$ ,  $Mg^{2+}$ , and small anions take part in counterbalancing, and that changes in the concentrations of all these ions in the stroma are accompanied by passive  $H^+$ ,  $K^+$ ,  $Cl^-$ , and probably  $Na^+$  transport across the envelope of intact chloroplasts.

The activity of various channels has been reported using electrophysiology in the outer envelope, inner envelope, and the thylakoid membrane (Segalla et al., 2005 and references therein). This includes  $Cl^-$ ,  $K^+$ , divalent cation-selective and light-induced channels. By allowing specific ion fluxes across plastidial membranes, these ion channels may either directly or indirectly regulate photosynthesis. Segalla et al. (2005) also described the effects of various channel modulators on photosynthetic oxygen evolution, when added to isolated chloroplasts or thylakoid membranes. The observed effects were only modest, and are explained by the fact that a complete inhibition of photosynthesis cannot be expected even by completely inhibiting channel activity, since these channels are not part of the photosynthetic machinery itself and their function probably is not mandatory for photosynthesis to occur. The activity of a gated  $K^+$  channel has been reported in the thylakoid membrane (Tester and Blatt, 1989; Fang et al., 1995). This protein was supposed to mediate  $K^+$  efflux from the thylakoid lumen to charge balance the light-induced  $H^+$  gradient across the membrane. Its activity has been shown to be required for optimal  $O_2$  evolution, and to be regulated via ATP-dependent phosphorylation rather than voltage.

In animal and plant cells, anion channels/transporters play a role in the maintenance of electrochemical gradient and in signaling pathways allowing adaptation to stress of both biotic and abiotic type. They play various physiological roles in stomata opening, plant–pathogen interaction, compartmentation of metabolites and coupling with  $H^+$  gradient (De Angeli et al., 2007, 2009a). Channels from the plasma membrane are best characterized, using electrophysiological techniques, but, in most cases, the proteins responsible are not identified. Chloride channel (CLC) family comprises seven members in *Arabidopsis*, present in various membrane compartments, namely, vacuoles (AtCLCa), Golgi (AtCLCd and AtCLCf), and thylakoid membrane (AtCLCe) (Hechenberger et al., 1996; De Angeli et al., 2009a). The vacuolar AtCLCa member was shown to function as a  $2NO_3^-/H^+$  exchanger, and therefore, proposed to play a role in nitrate homeostasis (Geelen et al., 2000). Most recently, it has been reported that ATP binding to this protein regulates its transport activity (De Angeli et al., 2009b). The AtCLCe member is targeted to the thylakoid membranes in chloroplasts (Marmagne et al., 2007). In agreement with this subcellular localization, AtCLCe expression is higher in green tissues compared with roots, and the *clce* mutants display a phenotype related to photosynthetic activity, namely, a slower polyphasic chlorophyll fluorescence induction. Although no direct evidence for anion currents in *Arabidopsis* photosynthetic thylakoid membranes has been provided so far, anion channel activities have been previously reported on thylakoid membranes by Schönknecht et al. (1988) in the higher plant *Peperomia metallica*, and by Potossin and Schönknecht (1995, 1996) in the alga *Nitellopsis obtusa*. Changes in the intra-thylakoid ionic status are expected to occur in *clce* mutant, which could indirectly alter the kinetics of fluorescence induction. A direct effect is expected on the overall architecture of the thylakoid, since the formation of the grana stacks is known to depend on the ionic strength.

AtCLCe has been predicted to function as a voltage-gated CLC in thylakoids (Figure 14.3), supporting very specific biological functions, but not anion accumulation. Most recently, Monachello et al. (2009) proposed that, in chloroplasts,  $Cl^-$  and, most probably  $NO_2^-$ , are good candidates as counter-anions able to compensate for the excess positive charges in the thylakoid lumen. In this situation, alterations in ionic strength or osmotic properties of chloroplast compartments may, in turn, directly or indirectly increase the nitrite level, most probably in the cytosol, as exhibited by both *clce* and *clca* mutants. This might suggest a role for AtCLCe in nitrite translocation from the stroma into the thylakoids, taking over from the nitrite transporter of the chloroplast envelope (Sugiura et al., 2007). Analyses of T-DNA insertion *clca* and *clce* mutants revealed common phenotypic traits, including a lower endogenous nitrate content, a higher nitrite content, a reduced nitrate influx into the root, and a decreased expression of several genes encoding nitrate transporters (Monachello

et al., 2009). This set of nitrate-related phenotypes point to interconnecting roles of AtCICa and AtCICe in nitrate homeostasis, involving two different endocellular membranes.

#### 14.5.1.2 Aquaporins

A total of 35 aquaporins (AQP, T.C. #1.A.8), also known as major intrinsic proteins (MIP) have been identified in *Arabidopsis* by genome and transcriptome analysis, as compared to vertebrates for example where only 11–13 aquaporins exist (Kaldenhoff and Fischer, 2006; Wudick et al., 2009). Aquaporins transport water, but in some cases are also permeable for glycerol, urea, amino acids, and ions. Most recently, an aquaporin-sharing homology with the human aquaporin AQP1 has been identified in *Nicotiana tabacum*, and named NtAQP1. This protein has been initially localized to the plasma membrane, demonstrated to have a CO<sub>2</sub> transport function in *Xenopus* oocytes in addition to the water transport function, and shown that its high expression stimulates leaf photosynthesis and plant growth (Uehlein et al., 2003). Because of its location at the plasma membrane, NtAQP1 has been classified as a member of the plasma membrane intrinsic protein (PIPI) family, and it has been assumed that its function in CO<sub>2</sub> transport takes place in this membrane. This view has been revisited by Uehlein et al. (2008). Using immunogold localization of the native protein, and fluorescence microscopy of transiently expressed NtAQP1–GFP, these authors deduced localization for the protein at the plasma and inner envelope chloroplast membranes of tobacco mesophyll cells. They proposed that the dual localization of NtAQP1 is accompanied by a functional switch from a water channel (at the plasma membrane) to a CO<sub>2</sub> channel (at the chloroplast envelope). Thus, the envelope NtAQP1 has an important physiological function by facilitating CO<sub>2</sub> transport through the leaf to the site of CO<sub>2</sub> fixation in the stroma. Using RNA interference approach, it has been shown that plants with reduced expression levels of NtAQP1 increase by 90% the resistance to CO<sub>2</sub> of chloroplast membranes, hence reduce the rate of photosynthesis. These findings have challenged the concept of free diffusion of CO<sub>2</sub> through biological membranes, and expanded the substrate specificity of aquaporins to gases in an organelle where CO<sub>2</sub> plays the role of a substrate.

Several AQPs, including tonoplast intrinsic proteins AtTIP1;1, and TIP2;1 and plasma membrane intrinsic protein AtPIPI;1, have also been detected in a proteomic analysis of the *Arabidopsis* chloroplast envelope (Ferro et al., 2003). Although purification procedures for *Arabidopsis* chloroplasts have been highly optimized, these proteins were initially considered as extra-plastidial contaminants (e.g., Beebo et al., 2009). Given the recent data on the dual localization of NtAQP1, it needs to be reexamined whether the proteomic detection of those TIP and PIP proteins reflects their actual presence in chloroplast membranes.

#### 14.5.1.3 Translocon of the Inner Envelope Anion Channel 110 (Tic110)

The Tic110 protein of the inner chloroplast envelope membrane (T.C. #1.A.18) has been proposed to be a channel-forming protein at the inner envelope of chloroplasts, whose function is essential for the import of proteins synthesized in the cytosol. Tic110 appears to be the protein-import-related anion-selective channel (van den Wijngaard and Vredenberg, 1999). Most recently, its topology has been revealed as well as its regulation by stromal Ca<sup>2+</sup> ions and stromal thioredoxin (Balsera et al., 2009). Phenotypic analysis of knock-down mutants indicated a disturbed assembly of the Tic complex and reduction in the levels of a wide variety of plastid proteins (Inaba et al., 2005). Knockout homozygous *tic110* embryos exhibited retarded growth and arrest at the globular developmental stage, whereas heterozygous *tic110* plants exhibited chlorosis, aberrant chloroplast biogenesis, and inefficient chloroplast-import of both photosynthetic and non-photosynthetic preproteins (Kovacheva et al., 2005). Taken together, these data indicate an essential role for Tic110 in plastid biogenesis and plant viability.

#### 14.5.1.4 Mg<sup>2+</sup> Channel (MRS)

Magnesium (Mg<sup>2+</sup>) is essential for many plant processes. It is particularly important for photosynthesis, where it is the central element of the chlorophyll molecules. Besides this, Mg<sup>2+</sup> is also a

constituent of many enzymes and serves as an activator of others, including DNA polymerases, protein kinases, and phosphatases. Despite these critical cellular functions,  $Mg^{2+}$  uptake, transport, and homeostasis in eukaryotes are poorly understood at both the physiological and the molecular level.

CorA metal ion transporters (T.C. #1.A.35) represent a large and diverse family with sequenced members in Gram-positive and Gram-negative bacteria, cyanobacteria, archaea, plants, animals, and yeast. Their biochemical function is to transport  $Mg^{2+}$ ,  $Co^{2+}$ ,  $Ni^{2+}$ , and  $Zn^{2+}$ , but not  $Fe^{2+}$  ions. The bacterial protein CorA, present in a wide range of bacterial species, is the best-characterized  $Mg^{2+}$  channel to date (Moomaw and Maguire, 2008). The CorA homologue MRS2 represents the mitochondrial  $Mg^{2+}$  channel in all eukaryotes, and is essential for cell survival. The *Arabidopsis* homologue MRS2-11 was localized to chloroplasts, and when expressed in yeast, it was shown to transport  $Mg^{2+}$  (Drummond et al., 2006). Using RT-PCR, it was demonstrated that the expression of this gene follows circadian rhythm, with a twofold higher steady-state expression in the light. No phenotype related to  $Mg^{2+}$  content and fluorescence yield was detected in plants over-accumulating the AtMRS2-11 protein. Therefore, no *in planta* role in  $Mg^{2+}$  homeostasis has been so far established for this gene.

#### 14.5.1.5 Outer Envelope Porins

The outer envelope membrane has long been assumed to be freely permeable for solutes with molecular weight of up to 10kDa. Correspondingly, it has been believed that the osmotic barrier against the cytosol is formed exclusively by the inner envelope. In Gram-negative bacteria, however, several different types of high-conductance channels exist in the outer membrane, such as porins, porin-like channels, and ligand-gated pores (Nikaido, 2003). The ancestral relation between plastids and Gram-negative bacteria, therefore, suggests the presence of multiple channel proteins in the chloroplast outer membrane. Indeed, the membrane-intrinsic outer envelope proteins (OEPs) form solute channels with properties reminiscent of porins and channels in the bacterial outer membrane. OEP channels are  $\beta$ -barell protein (T.C. #1.B.), and are characterized by distinct specificities for metabolites and a quite peculiar expression pattern in specialized plant organs and plastids, thus disproving the assumption that the outer envelope is a nonspecific molecular sieve (Duy et al., 2007a).

The  $\alpha$ -helical OEP16 forms a cation-selective high-conductance channel with a remarkable permeability for amino acids and amines. OEP16 from pea is best characterized, and shown to be voltage-sensitive, and impermeable to triose-phosphate and uncharged sugars (Pohlmeyer et al., 1997). In contrast, OEP21 has been shown to form an anion channel, which is regulated by ATP and triose-phosphate from the intermembrane space (Hemmler et al., 2006). The channel properties of OEP24, however, closely resemble those described for general diffusion pores. OEP24 allows the passage of triose-phosphate, ATP, PPI, dicarboxylate, and positively or negatively charged amino acids (Pohlmeyer et al., 1998). In summary, these findings indicate that the intermembrane space of chloroplasts is not freely accessible to low-molecular-weight solutes. Goetze et al. (2006) reported that OEP37 forms a rectifying, cation-selective, high-conductance channel, which is sensitive to peptides and may function during seed development and germination of *Arabidopsis* plants. Transcripts of AtOEP37 are ubiquitously expressed throughout plant development, and accumulate in early germinating seedlings as well as in late embryogenesis. However, phenotypic analyses of the knockout mutant *oep37-1* showed that the proper function of this single-copy gene is not essential for development of the mature plant. Thus, OEP37 may constitute a novel peptide-sensitive ion channel in the outer envelope of plastids with function during embryogenesis and germination.

### 14.5.2 SECONDARY TRANSPORTERS

Secondary or electrochemical-driven transporters (T.C. #2) work using the concentration gradient of cotransported molecules. The major facilitator superfamily (MFS, T.C. #2.A.1) represents the largest secondary transporter family (over 10,000 sequenced members) in all organisms including plants. Its members transport a wide variety of substrates, including carbohydrates, phosphates, amino acids, and cations. Protons and  $Na^+$  ions are commonly used as cotransported molecules by 80% of

the MFS members. If bacteria and plants mostly use  $H^+$ , animals use  $Na^+$  ions as the cotransported molecule. Nevertheless, there is an increasing number of  $Na^+$ -dependent transport systems described in plants, including phosphate transporters, organic acid transporters, and NhaD antiporter (Ruiz Pavón et al., 2008; Nagata et al., 2008). Most MFS members consist of 400–600 amino acid residues and possess either 12, 14, or 24 putative transmembrane  $\alpha$ -helical spanners. MFS antiporters operate *via* a single binding site, and an alternating-access mechanism, which involves a rocker-switch type movement of the two halves of the protein (Law et al., 2008). Salt-bridge formation and breakage are involved in the conformational changes of the protein during transport. Chloroplast secondary transporters belonging to various subclasses are described below and summarized in Table 14.3.

#### 14.5.2.1 Phosphate Transporters

Inorganic phosphate ( $P_i$ ) is an essential nutrient for plants and has both structural and regulatory roles, including modulation of photosynthesis. The concentration of  $P_i$  has to be maintained within relatively narrow limits, and this is achieved through metabolic recycling and transport across cellular membranes. Phosphate transporters are essential for chloroplasts since they control the  $P_i$  level in the stroma and the homeostasis required to initiate the Calvin cycle. Combination of experimental evidence and genome sequence analysis indicate that plants contain a wide variety of  $P_i$  transporter genes. So far, five distinct families of  $P_i$  transporters have been characterized, namely, PHT1 to PHT4 and pPT, each of them composed of multiple members (Rausch and Bucher, 2002; Knappe et al., 2003a; Guo et al., 2008a). Members of the PHT1 family are located in the plasma membrane and mediate  $P_i$  uptake into cells, whereas members of PHT2, PHT3, PHT4, and pPT families mediate translocation of  $P_i$  across organellar membranes. PHT2, pPT, and three out of the six PHT4 members (PHT4;3, PHT4;4 and PHT4;5) are chloroplast inner envelope proteins, whereas one PHT4 member is a thylakoid protein (Ruiz Pavón et al., 2008). PHT3 members are located to the inner mitochondrial membrane.

##### 14.5.2.1.1 Major Facilitators

PHT4 family is the most recently characterized PHT family (Guo et al., 2008a). It belongs to MFS and shares similarities with the mammalian SLC17/type I  $P_i$  transporters (T.C.#2.A.1.14.13). Therefore, PHT4 has been initially annotated as the anion transporter (ANTR) family. However, in contrast to SLC17, which has broad substrate specificity ( $P_i$ , organic anions and chloride), PHT4 members have been characterized in both yeast and *E. coli* as specific  $P_i$  transporters (Guo et al., 2008a; Ruiz Pavón et al., 2008). The difference between the two expression systems was in the nature of the cotransported ion since the first member (PHT4;1 *alias* ANTR1) has been characterized as a  $H^+$ -dependent  $P_i$  transporter in yeast and as a  $Na^+$ -dependent one in *E. coli*. Five of the six PHT4 members are targeted to plastids, and the sixth one to the Golgi (Guo et al., 2008a).

Among the plastid members, PHT4;2 (ANTR3) was exclusively found in the roots, whereas the other four are present in both leaves and roots but predominate in leaves, indicating a main function in the chloroplast. Two plastid members have been assigned a specific intra-chloroplast location, namely, PHT4;1 and PHT4;4 (ANTR2), localized to the thylakoid and envelope membrane, respectively (Ferro et al., 2003; Roth et al., 2005; Ruiz Pavón et al., 2008; Bräutigam et al., 2008). PHT4;1 has been shown to have a circadian-rhythm-regulated expression pattern (Guo et al., 2008b).

The function of none of the PHT4 members has been studied in *Arabidopsis* organelles, but it is expected that the direction of  $P_i$  transport is regulated either by the  $H^+$  or  $Na^+$  ions gradient. Whether these ions are cotransported with  $P_i$  by PHT4 members has not been demonstrated either. Most recently, site-directed mutagenesis of the AtANTR1 has revealed important residues for its transport activity (Ruiz Pavón, Karlsson et al., 2009). In plants, PHT4;1 is proposed to recirculate  $P_i$  from the lumen to the stroma during ATP transport and GTP signaling across the thylakoid membrane (Figure 14.3 and Section 14.4), whereas PHT4;4 has been proposed to supply stroma with cytosolic  $P_i$  (Guo et al., 2008a). Knockout mutants of PHT4;1 display reduced growth and high levels of photoprotection (Karlsson et al., 2010).

Combining proteomics and *in silico* approaches, a number of Na<sup>+</sup>-dependent putative transporters have been identified in the chloroplast inner envelope membranes, such as Na<sup>+</sup>Pi transporter, Na<sup>+</sup>/taurocholate transporters, Na<sup>+</sup>/H<sup>+</sup> antiporter, and Na<sup>+</sup>-ascorbate transporter (Ferro et al., 2003). Although their role in chloroplast is not clear, their homologues in bacteria or animal system are known to play a role in pH and Na<sup>+</sup> homeostasis.

#### 14.5.2.1.2 Drug/Metabolite Transporters

The plastid phosphate transport (pPT) family is part of the drug/metabolite transporter (DMT) superfamily (T.C. #2.A.7). The pPT family consists of 16 members in *Arabidopsis*, and among them, 10 are probably pseudogenes (Knappe et al., 2003a). pPTs function as antiporters using Pi and phosphorylated compounds as counter-substrates. The most prominent member of the pPT family in the chloroplast envelope is the triose-phosphate/phosphate (TPT) antiporter. It was the first plant transporter cloned and with the primary sequence determined (Flügge et al., 1989). TPT has the role to export dihydroxy-acetone-phosphate generated during Calvin cycle to the cytosol, where it is used for sucrose and cell wall biosynthesis. It has been reported to be a voltage-dependent ion channel permeable to anions as well as an antiporter (Flügge, 1999). A single gene for TPT is present in *Arabidopsis* and is expressed in photosynthetically active tissues. TPT provides a link between chloroplast and cytosolic metabolism. A moderate reduction in the TPT activity leads to drastic perturbations of the leaf metabolism, since the lack of TP export for cytosolic sucrose biosynthesis appears to be compensated by continuous accelerated starch turnover as well as by export of neutral sugars from the stroma throughout the day. The utilization of glucose 6-phosphate (generated from exported glucose) rather than TP for sucrose biosynthesis in the light bypasses the key regulatory step catalyzed by cytosolic fructose 1,6-bisphosphatase (Schneider et al., 2002). Interestingly, the *ape2* mutant, carrying an insertion in the TPT gene, displayed altered photoprotection during growth light conditions (Walters et al., 2003). Furthermore, overall reduced rates of electron transport, due to reduction in PSII photochemical efficiency, was observed in the *ape2* mutant, and therefore proposed that export of photosynthetic products from the chloroplast *via* TPT is crucial for the maintenance of high rates of photosynthetic electron transport.

Another well-characterized phosphate transporter is phosphoenolpyruvate/phosphate transporter (PPT), which imports phosphoenolpyruvate (PEP) from the cytosol and drives fatty acid synthesis and synthesis of compounds by the shikimate pathway (e.g., aromatic amino acids). A third phosphate transporter is glucose-6-phosphate/phosphate antiporter (GPT), present only in heterotrophic plastids. In *Arabidopsis*, two genes coding for PPTs exist, namely, AtPPT1 and AtPPT2. The phenotype of the *cuel* mutant, carrying an insertion in the PPT1 gene, revealed impaired leaf development. Obviously, in *Arabidopsis*, there are no known metabolic pathways or transporters that can compensate for the loss of AtPPT1, including AtPPT2. Despite a low sequence similarity, both PPTs are located in chloroplasts and possess similar substrate specificities. Expression of the two PPT genes is distinct in different tissues and cell types (Knappe et al., 2003b). The *AtPPT1* gene was found expressed in all organs examined, whereas *AtPPT2* transcripts could be detected only in leaves and flowers. Because a functional AtPPT1 is obviously crucial for correct leaf development, it is suggested that AtPPT1 is presumably involved in the synthesis of secondary metabolites that trigger leaf development (Knappe et al., 2003b).

#### 14.5.2.1.3 Inorganic Phosphate Transporters

PHT2;1 is a low-affinity transporter belonging to the Pi transporter family ((PiT; T.C. #2.A.20). It is expressed in both autotrophic and heterotrophic tissues, and its expression in leaves is up-regulated by light (Rausch et al., 2004). However, the use of inhibitors of photosynthesis did not interfere with the expression, indicating that it is not the photosynthesis *per se* that increases the expression. Moreover, modulation of its expression did not have any impact on the photosynthetic activity. Instead, it has been proposed that Pi import *via* PHT2;1 counterbalances the ADP/ATP exchange

mediated *via* the ADP/ATP translocator (see below), and thus maintain the Pi homeostasis in both green and non-green tissues.

#### 14.5.2.2 ATP/ADP Antiporters

Nucleotides are essential for living cells, since they are the building blocks for nucleic acids, drive energy-dependent processes, and play critical role in signal transduction. Moreover, they also serve as cofactors for various enzymes such as nicotinamide adenine dinucleotides used for redox reactions. Nucleotides are essential in all organelles and require specific transporters.

Two structurally and phylogenetically different types of intracellular adenine nucleotide transporters have been identified in chloroplasts, belonging to either the ATP/ADP antiporter (AAA) family or to the mitochondrial carrier family. The ATP/ADP antiporters (T.C. #2.A.12) import ATP in exchange for ADP, reside in the plastid inner envelope membrane of plants, and originate from the cytoplasmic membrane of parasite bacteria (Winkler and Neuhaus, 1999). The activity of a spinach plastidic ATP/ADP translocator was characterized already in 1969 by Heldt, as supplying the stroma with ATP from the cytosol during the dark period (Heldt, 1969). The responsible proteins were later identified in *Arabidopsis*, and named plastidic nucleotide translocators AtNTT1 and AtNTT2 (Kampfenkel et al., 1995; Möhlmann et al., 1998).

The activity of AtNTTs is important in several types of plastids, such as amyloplasts and chloroplasts, and their major physiological role is to supply plastids with ATP. *AtNTT1* transcript accumulates in leaf discs at high sugar concentrations, indicating that this gene belongs to a group of sugar up-regulated genes that reprogram chloroplasts into starch-storing plastids. Expression of *AtNTT2* is up-regulated in root tips and cotyledons of developing seedlings (Reiser et al., 2004). In adult plants, *AtNTT2* transcript is present in similar amounts in roots, leaves, stem, and flower tissues. Plants lacking a functional *AtNTT1* gene did not show altered root formation, chlorophyll synthesis, or seedling development, correlating with the higher expression of the *AtNTT2* gene in those tissues (Reiser et al., 2004). Instead, inactivation of the *AtNTT2* gene resulted in impaired formation of roots, most likely due to an inhibited rate of fatty acid synthesis in root plastids, which had been shown to be strictly dependent on the external supply of ATP. Furthermore, phenotypic analyses of *AtNTT2* knockout mutants indicated a reduced amount of thylakoid structures in the early developmental stage. The same authors have suggested that AtNTT2 is involved in supplying ATP for chlorophyll synthesis and the import of nuclear-encoded thylakoid proteins, and that alternative ATP transport pathways cannot compensate for this activity.

#### 14.5.2.3 Mitochondrial Carriers

The mitochondrial carriers (MC; T.C. #2.A.29) are proteins found only in eukaryotic cells. As the name indicates, the proteins belonging to this family were first recognized in the mitochondrial inner membrane. In addition to the mitochondrion, such carriers have also been found in the peroxisome, hydrogenosome, amyloplast, and chloroplast (Laloi, 1999; Thuswaldner et al., 2007; Palmieri et al., 2009). The *Arabidopsis* genome contains 58 membrane proteins belonging to MC family. The most studied MC members are the mitochondrial ADP/ATP carriers (AAC; T.C. #2.A.29.1.1). Like the members of the AAA family, AACs are antiporters, but the direction of transport is opposite, i.e., they import ADP into the matrix and export ATP to the cytosol through the intermembrane space. At least five AACs have been predicted in *Arabidopsis* by alignment with orthologous sequences, and some of them have been heterologously expressed and functionally characterized (Picault et al., 2004).

The activity of the first chloroplast MC member was reported in the spinach thylakoid membrane (Spetea et al., 2004), transporting ATP into the lumenal space. Searching for proteins responsible for this transthylakoid activity, one candidate in *Arabidopsis* was found and named thylakoid ATP/ADP carrier (TAAC) (Thuswaldner et al., 2007; Figure 14.3). The protein has been localized to the thylakoid membrane using immunogold labeling, Western blotting, and most recently using proteomics (Thuswaldner et al., 2007; Zybailov et al., 2008). A recombinant AtTAAC protein was

heterologously expressed in *E. coli* and found functionally inserted into the cytoplasmic membrane, allowing uptake studies to be performed in intact cells. Such experiments revealed an ATP/ADP exchange type of transport.

The *AtTAAC* gene is highly expressed in young photosynthetic organs, such as developing leaves, flower buds, and green siliques (Thuswaldner et al., 2007). Therefore, a role for TAAC in thylakoid biogenesis was proposed. TAAC expression is strongly up-regulated in leaves undergoing senescence or exposed to wounding, light stress, oxidative stress, salt stress, and desiccation, pointing to an additional role in supplying ATP for energy-dependent processes during thylakoid turnover. Detailed phenotypic analyses of two *taac* knockout mutants indicated a reduced ATP transthylakoid transport, better photoprotection during short-term high light stress, and increased sensitivity to prolonged high light stress as compared to the wild type (Thuswaldner et al., 2007; Yin et al., 2010). In the *taac* mutant, the PSII repair cycle is impaired, most likely not due to a blockage of D1 protein synthesis, but rather due to an inhibition of its degradation (see also Section 14.4).

The Brittle 1 (BT1) protein is an adenine nucleotide uniporter, in contrast to most MCs functioning as antiporters. It was found in potato, maize, and rice, and a putative homologue exists in *Arabidopsis* (Leroch et al., 2005). BT1 from *Zea mays* has been shown to transport ADP-glucose into endosperm plastids, and participate in starch biosynthesis (Kirchberg et al., 2007). The potato orthologue (StBT1) exports adenine nucleotides synthesized in plastids to the cytosol to be used in a variety of metabolic processes, and has a similar affinity for AMP, ADP, and ATP. As compared to TAAC, the expression of *StBT1* gene is similar in root, stem, leaf, and flower (with highest expression in flowers), indicating a general role in plant metabolism (Leroch et al., 2005).

Other two MC members in *Arabidopsis* have been characterized as NAD<sup>+</sup> carrier proteins, one in the chloroplast inner envelope membrane (AtNDT1) and one in mitochondria (AtNDT2) (Palmieri et al., 2009). Both carriers transport NAD<sup>+</sup> in counter-exchange with ADP or AMP, are highly expressed in metabolically active cells, and proposed to play a role in NAD<sup>+</sup>-dependent metabolic pathways and in the redox balance of chloroplasts and mitochondria.

#### 14.5.2.4 The Monovalent Cation:Proton Antiporter-2 (CPA2)

Na<sup>+</sup>/H<sup>+</sup> antiporters influence H<sup>+</sup> or Na<sup>+</sup> ion motive force across the membrane. Recently, such a protein (NhaS3) has been localized to the thylakoid membrane of *Synechocystis* sp. PCC 6803 (Tsunekawa et al., 2009). It belongs to the monovalent cation:proton antiporter-2 family (CPA2, T.C. #2.A.37). Its expression has been found regulated by the circadian rhythm, and it has been proposed to function as a putative uncoupler of the electrochemical proton gradient generated during photosynthesis. The closest *Arabidopsis* homologue of this cyanobacterial transporter is AtCXH23 reported to localize to the envelope (Song et al., 2004). RNA interference inhibition of its expression leads to morphological changes in the chloroplast. Plastids from *chx23* mutants had straight thylakoids but lacked grana lamellae. The *chx23* mutant leaves were pale yellow and had reduced chlorophyll content. The cytosolic pH in the leaves of the mutant was significantly higher than that in the wild type. *chx23* mutants displayed a high sensitivity to NaCl. CHX23 is a probable chloroplast Na<sup>+</sup>(K<sup>+</sup>)/H<sup>+</sup> exchanger important for pH homeostasis and chloroplast development and function.

Although most plants have been reported to have a low Na<sup>+</sup> content in chloroplast stroma, it is possible that sequestration of this ion into chloroplasts occurs as a partial detoxification mechanism in *Arabidopsis* or most other plants. Although a thylakoid Na<sup>+</sup>/H<sup>+</sup> antiporter has not been yet identified in *Arabidopsis*, such an activity is required, as judged, for example, on the presence of a Na<sup>+</sup>-dependent Pi transporter (Ruiz Pavón et al., 2008), supposed to eliminate Na<sup>+</sup> from the lumen. In addition, it has been reported that NaCl stress inactivates PSII oxygen-evolving complex as well as PSI electron transport in *Synechococcus* sp. PCC 7942. This effect is prevented by the addition of Na<sup>+</sup>-channel and water channel blockers, indicating that NaCl has both osmotic and ionic effects (Allakhverdiev et al., 2000).

### 14.5.3 PRIMARY TRANSPORTERS

Primary transporters (pumps, T.C. #3) directly use energy to transport molecules across a membrane. Most of the enzymes that perform this type of transport are transmembrane ATPases. A primary ATPase universal to all cellular life is the  $\text{Na}^+/\text{K}^+$  pump, which helps to maintain the cell potential. Other sources of energy for primary active transport are redox energy and photon energy (light). An example of primary active transport using redox energy is the mitochondrial electron transport chain, which uses the reduction energy of NADH to move protons across the inner mitochondrial membrane against their concentration gradient. An example of primary transport using light energy is the photosynthetic electron transport chain that uses the energy of photons to translocate  $\text{H}^+$  across the thylakoid membrane, also against their concentration gradient, and results in the production of reducing power in the form of NADPH. Chloroplast pumps belonging to various subclasses are described below and summarized in Table 14.4.

#### 14.5.3.1 ATP-Binding Cassette Transporters

ABC proteins (T.C. #3.A.1) represent one of the largest known families of proteins, and are present in bacteria, fungi, animals as well as plants (Martinoia et al., 2002). Most members are transporters that use the energy of ATP hydrolysis for driving translocation of various substrates. Characteristic for ABC transporters is their ability to use other nucleotides, mainly GTP, as a substitute for ATP, and the inhibition of their activity by vanadate. They participate in various processes, such as excretion of toxic substances, lipid translocation, conferring heavy-metal tolerance, antigen presentation, and exhibiting ion channel activity (Martinoia et al., 2002).

Among the 103 predicted ABC transporters in *Arabidopsis*, 14 were predicted as chloroplast proteins (Spetea and Thuswaldner, 2008). A few of them have been identified in chloroplast envelope membranes by proteomics (Kleffmann et al., 2004), but none of them has been characterized in terms of substrate and transport properties.

#### 14.5.3.2 $\text{H}^+$ -Translocating F-Type ATPases

The F-type ATPases ( $\text{F}_0\text{F}_1$ -ATPase; T.C. #3.A.2.1.1) generate ATP from ADP and phosphate, using the electrochemical proton gradient as a driving force. Thus,  $\text{F}_0\text{F}_1$  is an enzymatic machinery combining mechanical, electrical, and chemical aspects. The electrochemical motif force powers the electrical rotary motor  $\text{F}_0$ , driving in its turn the chemical motor  $\text{F}_1$  to produce ATP.  $\text{F}_0\text{F}_1$  can work in either direction, depending on which driving force dominates (unless is down-regulated for ATP hydrolysis, as in chloroplasts). The latest insights into the rotary mechanism of this machinery have been reviewed, revealing torque generation and an elastic mechanical-power transmission from  $\text{F}_0$  to  $\text{F}_1$  (Junge et al., 2009). The elastic power transmission between the two motors is proposed to smooth their cooperation without the need for fine tuning.

$\text{F}_0\text{F}_1$ -ATPases are present in both prokaryotic and eukaryotic organisms, localized in energy-transducing membranes, such as the chloroplast thylakoid membrane, the mitochondrial inner membrane, and the cytoplasmic membrane of some bacteria. The chloroplast ATP synthase ( $\text{CF}_0\text{F}_1$ -ATPase) is located in the thylakoid membrane, completing the energy transduction of the electron transport chain by synthesizing ATP (Figure 14.3 and Nelson and Ben-Shem, 2004). Six subunits of the chloroplast ATP synthase are chloroplast encoded, while only three subunits are nuclear-encoded proteins. The gamma subunit has been shown to be crucial for photoprotection, since its inactivation by T-DNA insertion mutagenesis destabilized the entire ATP synthase complex, and abolished the photophosphorylation reaction. Instead, a high level of proton accumulation was observed in the thylakoid lumen leading to swollen thylakoids and unusually high levels of NPQ of chlorophyll fluorescence (Bosco et al., 2004). Although there are no reports on mutagenesis of other major subunits of the ATP synthase subunits from *Arabidopsis*, it is expected that the effects would be very similar to those observed for the gamma subunit.

The activity of a chloroplast inner envelope  $H^+$ -ATPase has been also reported in the past (Berkowitz and Peters, 1993). It transports  $H^+$  from the stroma to the cytosol using the energy of ATP hydrolysis to maintain a pH gradient between stroma and cytosol, and thus optimize photosynthetic capacity. However, the protein components of the envelope  $H^+$ -ATPase have not yet been identified.

#### 14.5.3.3 P-Type ATPases

The P-type ATPase superfamily (P-ATPase, T.C. #3.A.3) consists of pumps transporting charged substrates, including  $H^+$ ,  $Na^+$ ,  $K^+$ ,  $Mg^{2+}$ ,  $Ca^{2+}$ ,  $Cu^{2+}$ ,  $Cd^{2+}$ ,  $Zn^{2+}$  ions, and phospholipids across membranes of both prokaryotes and eukaryotes. This superfamily includes a heavy-metal  $P_{1B}$ -ATPase (HMA) family that translocates cations out of the cytoplasm across biological membranes using energy from ATP hydrolysis. Among the 46 P-ATPases predicted in *Arabidopsis*, 3 have been so far identified and characterized in the chloroplast inner envelope membrane, namely, the  $Cu^{2+}$ -ATPase PAA1 (Shikanai et al., 2003), the  $Cu^{2+}$ ,  $Ca$ , and  $Zn^{2+}$ -ATPase HMA1 (Seigneurin-Berny et al., 2006; Moreno et al., 2008; Kim et al., 2009), and the autoinhibiting  $Ca^{2+}$ -ATPase ACA1 (Huang et al., 1993), and 1 in the thylakoid membrane, namely, the  $Cu^{2+}$ -ATPase PAA2 (Abdel-Ghany et al., 2005) (Figure 14.3). Unlike other plant P-ATPases, HMA1 appears to have a broad substrate specificity, explained by the observed difference in amino acids important for substrate specificity, and by the fact that evolutionarily it is more ancient than other members of the HMA family (Kim et al., 2009).

PAA1 and PAA2 transport copper into the chloroplast, and further across the thylakoid membrane, supplying the lumen with this essential cofactor, which plays a role in the photosynthetic electron transport through the plastocyanin (Shikanai et al., 2003; Abdel-Ghany et al., 2005). Copper is also a cofactor for the chloroplast Cu/Zn-superoxide dismutase (SOD), critical for the defense against many oxidative stress situations (Bertrand and Poirier, 2005; see also Chapter 26). Analysis of *paal* knockout mutants revealed deficiency in photosynthetic electron transport, likely due to impaired import of  $Cu^{2+}$  into the chloroplast resulting in insufficient formation of holoplastocyanin and lack of Cu/Zn-SOD in green tissues (Shikanai et al., 2003; Abdel-Ghany et al., 2005). The *paal2* mutant had a similar, though not as severe, phenotype. The double *paal1-2* mutant was seedling lethal (Abdel-Ghany et al., 2005). The *hma1* knockout plants were shown to be photosensitive under high light, consistent with the decrease in the chloroplast copper content and reduction in the total chloroplast SOD activity (Seigneurin-Berny et al., 2006). Furthermore, the ATPase activity of HMA1 was shown to be lower than that of PAA1, though they were not able to replace each other. These results suggest that, though functional in the same (envelope) membrane, PAA1 is the main  $Cu^{2+}$ -ATPase, whereas HMA1 may play a different role in chloroplasts. Most recently, it has been shown that when grown in the presence of high  $Zn^{2+}$  concentrations, the *hma1* mutant displays shoot weight and chlorophyll content that are below 40% of the wild type. The explanation of this phenotype is that the mutant accumulates more  $Zn^{2+}$  than the wild type in the shoot, and therefore it has been proposed that HMA1 protects the chloroplast against toxicity of  $Zn^{2+}$  by exporting it to the cytoplasm. No phenotype related to  $Cu^{2+}$ ,  $Ca^{2+}$ , or heavy metal has been found for HMA1 to support the  $Cu^{2+}$  and  $Ca^{2+}$ -transporting activity. The light-sensitive phenotype observed by Seigneurin-Berny et al. (2006) was explained by the fact that excess  $Zn^{2+}$  could replace  $Cu^{2+}$  in SOD.

#### 14.5.3.4 Light-Absorption-Driven Transporters

Light-absorption-driven transporters (T.C. #3.E) are transport systems that utilize light energy to drive transport of a solute, and are divided in two subclasses: the ion-translocating rhodopsin family (T.C. #3.E.1) and the photosynthetic reaction center (PRC, T.C. #3.E.2). There are two types of PRCs in the chloroplast thylakoid membrane, associated with PSII and PSI. They use the energy of absorbed photons to translocate electrons across the membrane. Similarly, bacterial RCs together with the cyt *b<sub>6</sub>f* complex mediate the conversion of light into electrochemical energy by transmembrane electron and  $H^+$  transport during photosynthesis. In this process, electron transfer to quinone

is coupled to proton transfer. Both PSI and PSII of plants and cyanobacteria belong to the PRC superfamily, but they are more complex than the purple bacterial members. The reaction center subunits of PSII are D1 and D2, which bind/contain the redox components in the electron transfer chain. D1 is the most important subunit for PSII since it binds most of the active components, is most prone to photodamage, and requires efficient repair in order that the organism survives in its natural or stressful light environment (see Section 14.2).

#### 14.5.4 INCOMPLETELY CHARACTERIZED TRANSPORTERS

Transport protein families of unknown classification (T.C. #9) are grouped in this category, and will hopefully be classified elsewhere when the transport mode and/or energy coupling mechanism will be characterized. These families include at least one member for which a transport function has been established, but neither the mode of transport nor the energy coupling mechanism is still known. To this category belong the chloroplast metal ion transporters described in Section 14.5.4.1 and summarized in Table 14.4.

##### 14.5.4.1 Metal Ion Transporters

Transition metal transporters maintain metal concentration within physiological limits in all plant organs where enzymes and proteins functionally associated with metals ( $\text{Zn}^{2+}$ ,  $\text{Cu}^{2+}$ ,  $\text{Fe}^{2+}$ ,  $\text{Mn}^{2+}$ , and  $\text{Ni}^{2+}$ ) are present. Particularly, the photosynthetic machinery in plants is abundant in metal-containing proteins, with  $\text{Fe}^{2+}$  being the dominant type in PSII, PSI, *cyt  $b_6f$* , and ferredoxin followed by  $\text{Mn}^{2+}$  in the oxygen-evolving complex of PSII, and  $\text{Cu}^{2+}$  in plastocyanin (Merchant and Dreyfuss, 1998). The reason why the three metal ions play a vital role in photosynthetic electron transport in chloroplasts resides in their potential for valency changes. There are many different known transition metal transport families (Krämer et al., 2007). It seems that there are specific characteristics for transporters of essential metals and for toxic metals from those for other small molecules or ions. For example, transition metal ions present in aqueous solution form in the cytoplasm can disrupt cellular functions. Based on metal-binding affinities of apo-metalloproteins, it has been estimated that the cytoplasmic concentrations can correspond to less than one free metal ion per cell. In other words, there is no persistent pool of free transition metal ions, from which metal transporters can bind metal ions. Instead, it is thought that these transporters acquire their metal substrates through interaction with metallochaperone shuttle proteins (O'Halloran and Culotta, 2000). Despite these essential functions for metal ions in photosynthesis, very little is known about metal transport proteins in chloroplasts. To date, the only chloroplast proteins demonstrated to be involved in metal ion transport are the  $\text{Mg}^{2+}$  transport protein MRS2-11, the  $\text{Cu}^{2+}$ -transporting P-type ATPases PAA1 and PAA2, and the heavy-metal ATPase HMA1, discussed in Sections 14.5.1.4 and 14.5.3.3.

Direct measurements of iron transport on isolated pea (*Pisum sativum*) chloroplasts have shown that iron is transported as  $\text{Fe}^{2+}$  ion across the inner envelope (Shingles et al., 2001, 2002). The putative metal uptake protein has been proposed to mediate  $\text{Fe}^{2+}/\text{H}^{+}$ -uniport and be able to transport  $\text{Zn}^{2+}$ ,  $\text{Cu}^{2+}$ , and  $\text{Mn}^{2+}$  ions as well. Recently, the responsible protein has been identified in the inner envelope of *Arabidopsis* chloroplasts and named Permease In Chloroplasts 1 (PIC1) (Duy et al., 2007b). PIC1 has a cyanobacterial origin, and most likely functions as an iron permease in the chloroplast envelope. The phenotype of *pic1* knockout mutants resembled that of iron-deficient chloroplasts, i.e., chlorosis, displayed an altered organization of leaf mesophyll cells, and severe defects in chloroplast and thylakoid development. Furthermore, the expression of photosynthetic and Fe-S cluster genes is down-regulated in the *pic1* mutants. Instead, the ferritin clusters accumulate in the mutant plastids and many stress-related genes are up-regulated, indicating an iron-overload reaction in the cytosol and impaired metal homeostasis at the cellular level. Both PIC1 and its cyanobacterial homolog (slr11656) have been found to perform iron uptake and to complement the growth of an iron-uptake-defective yeast mutant, indicating that the protein is involved in iron transport and homeostasis in chloroplasts.

PIC1 has also been known as TIC21, since it has been found to be involved in a 1 MDa translocation complex during protein import across the chloroplast inner envelope membrane (Teng et al., 2006; Kikuchi et al., 2009). The 1 MDa translocation complex is neither the Toc complex, to which preproteins initially bind, nor the Tic110-containing complex, which should mediate a later translocation step on the stromal side, but functions in between the Toc- and the Tic110-containing complexes. Based on phenotypic analyses of *tic21* alias *pic1* mutants, it has been shown that TIC21 is not central for the import, but most likely a loosely associated component. Moreover, the phenotype of the mutant was shown to resemble that of other albino mutants, and thus not directly related to iron homeostasis.

Another transporter with potential role in iron homeostasis is RTS3. This protein has been initially predicted as a chloroplast inner envelope protein and as an antibiotic (aminoglycoside) transporter (Aufsatz et al., 2009). The experimental proof for its location and function was brought by Conte et al. (2009). Therefore, RTS3 has been renamed to multiple antibiotic resistance 1 (MAR1). Based on the identified function and localization to the plant chloroplast, it is unlikely that evolutionary pressure has selected for mean of entry for toxic antibiotics into this organelle. The transport of antibiotics is most likely an opportunistic effect, explained by the fact that the prokaryotic and the chloroplast machineries are very similar and that the bacterial plasma membrane and the chloroplast (inner) envelope membrane contain similar types of transporters. The natural function of MAR1 is unknown, however, based on its similarity to ferroportin (T.C. #9.A.23), a function in  $\text{Fe}^{2+}/\text{H}^{+}$  antiport, and a role in cellular iron homeostasis have been proposed. The mutants overexpressing MAR1 show chlorosis, a common symptom of iron deficiency in plants since iron is essential for chlorophyll biosynthesis. Since this phenotype is rescued by iron feeding, MAR1 may play a role in iron chelation, storage, and/or sequestration. Thus, MAR1 may be transporting iron or a molecule (e.g., nicotinamide) involved in iron homeostasis into the chloroplast. MAR1 may not be able to distinguish between this molecule and aminoglycosides.

## 14.6 MODEL FOR THE ROLE OF THYLAKOID TRANSPORTERS IN LIGHT STRESS

The water-oxidizing PSII complex has attracted a special attention, since its reaction center D1 subunit is degraded and replaced much faster than the other subunits under excess and even optimal light conditions (see Section 14.2). Thus, D1 protein turnover is the major event in the repair cycle of the PSII complex, and occurs subsequently to the inactivation of PSII electron transport. D1 protein degradation is a multistep proteolytic event, requiring GTP and ATP, and performed most likely by Deg and FtsH proteases (Spetea et al., 1999; Lindahl et al., 2000; Haussühl et al., 2001; Silva et al., 2003; Kapri-Pardes et al., 2007). The PSII repair cycle is regulated by reversible phosphorylation of several core subunits, including D1 (Tikkanen et al., 2008). The repair process step-by-step could be described as follows: phosphorylation and damage of PSII dimers by high light in the grana thylakoids, monomerization and migration to the stroma thylakoids, dephosphorylation and dissociation of the CP43 subunit from the PSII core monomer, degradation of the D1 subunit; *de novo* synthesis of a new D1 protein; co-translational insertion of the D1 and concomitant assembly of the PSII monomer; migration back to the grana thylakoids, dimerization, and reactivation of the oxygen-evolving complex (Aro et al., 1993; Aro et al., 2005). The major steps are shown in Figure 14.4, where, for clarity, the phosphorylation/dephosphorylation events have been omitted.

To perform this multistep cycle in an efficient way for the plant to cope with the ambient light conditions, a large number of regulatory and transport proteins are required. Most of them are still unknown despite their crucial importance, in the frame of molecular agriculture, to obtain varieties with improved crop production and tolerance to stress. *Arabidopsis* has been an excellent model plant to identify such components with the help of available genomic information and a wide variety of genetic tools (see Section 14.3). Using a functional genomics approach, four thylakoid transporters have been identified and characterized at molecular level (see Figure 14.3). Special emphasis is

**FIGURE 14.4** Schematic model of the sequence of events during damage and repair of photosystem II (PSII) complex exposed to high light stress. Step 1: PSII inactivation, D1 protein damage, PSII monomerization, and migration to the stroma lamellae; Step 2: dissociation of CP43 and PsbO subunits from the PSII monomer, degradation of the D1 protein by Deg and FtsH proteases; Step 3: *de novo* synthesis and co-translational insertion of a new D1 protein, reassembly of the PSII monomer; Step 4: migration to the grana lamellae, dimerization, and activation. Based on very recent reports (see text for details), transthylakoid ATP transport and GTP signaling are proposed to play critical roles during PSII repair cycle as follows: ATP synthase supplies ATP in the stroma, which is translocated by the thylakoid ATP/ADP carrier (TAAC) into the lumen in exchange for ADP. The luminal nucleoside diphosphate kinase 3 (NDPK3) converts ATP to GTP, which is bound and hydrolyzed by the PsbO subunit extrinsic luminal subunit of PSII, leading to its dissociation and subsequent PSII disassembly (Step 2) in a highly controlled manner. The resulting phosphate (Pi) is exported back to the stroma by the Na<sup>+</sup>-dependent Pi transporter (ANTR1).

given in this section to TAAC and ANTR1, since both may play a role in PSII repair and photo-protection. Due to their transport activity, they may provide the link between ATP synthesis on the stromal side of the thylakoid membrane and nucleotide-dependent reactions in the luminal space.

A model for their function during PSII repair cycle is presented in Figure 14.4, and explained below. The ATP translocated by TAAC across the thylakoid membrane is converted to GTP by the luminal nucleoside diphosphate kinase 3 (NDPK3). GTP is, then, bound and hydrolyzed by the PsbO luminal extrinsic subunit of the PSII complex (Spetea et al., 2004; Lundin et al., 2007a). Between the two PsbO isoforms in *Arabidopsis*, it has recently been reported that PsbO2 plays an essential role in D1 turnover during high light stress and has a higher GTPase activity than PsbO1 (Lundin et al., 2007b, 2008; Allahverdiyeva et al., 2009). The precise mechanism of PsbO2-mediated PSII repair is not yet known. Nevertheless, GTP was previously reported to be required for efficient proteolytic removal of the D1 protein during repair of photoinactivated PSII (Spetea et al., 1999). Furthermore, it has been proposed that the PsbO2-type of PSII complexes undergo a more efficient repair due to the PsbO2-mediated GTPase activity that induces PsbO2 release from the complex, thus facilitating the next steps in the repair process, namely, dissociation of the CP43 subunit and proteolysis of the D1 subunit (Lundin et al., 2007b, 2008). The Na<sup>+</sup>-dependent Pi transporter ANTR1 is proposed to play a role in exporting back to the stroma Pi generated during nucleotide metabolism including GTP hydrolysis (Ruiz Pavón et al., 2008).

In addition to the role in PSII repair, both transporters appear to influence the thermal photo-protection during high light stress (Yin et al., 2010; Karlsson et al., 2010). At least in the TAAC case, this effect is attributed to the fact that its transport activity is driven by the H<sup>+</sup> gradient across the thylakoid membrane (Thuswaldner et al., 2007). It is well known that adenine nucleotide exchanged by AAC across the mitochondrial membrane is electrogenic (ATP<sup>4-</sup>/ADP<sup>3-</sup>) since only

the unprotonated species  $\text{ATP}^+/\text{ADP}^{3-}$  are transported independently of pH in the range 6.2–7.4 (Gropp et al., 1999). It is likely that this is also valid for TAAC-catalyzed transport taking into account the similar structure and antiport mechanism for AAC and TAAC (Thuswaldner et al., 2007). More recent studies have shown that ionic strength of the medium can broaden the pH range of unprotonated species toward pH 5 (De Stefano et al., 2006), which is relevant for the thylakoid lumen.

The transport activity of ANTR1 has been shown to be dependent on electrochemical  $\text{Na}^+$  gradient, when assessed across the bacterial membrane (Ruiz Pavón et al., 2008). Furthermore, based on the determined kinetics parameters, a stoichiometry of  $>1$  for  $\text{Na}^+:\text{Pi}$  for ANTR1-mediated transport has been suggested. There are reports indicating an electrogenic transport for other  $\text{Pi}$  transporters (Bacconi et al., 2005), but not specifically for the SLC17 family, to which ANTR1 belongs. Nevertheless, the observation that mutants lacking this protein display higher levels of NPQ than the wild type (Karlsson et al., 2010) points out to a possible electrogenic mechanism for the thylakoid  $\text{Pi}$  transporter as well. Thus, it appears that to maintain steady and balanced electrochemical gradient across the thylakoid membrane, electrogenic transporters may modulate the activity of the xanthophyll cycle (see Chapter 16). To summarize, the thylakoid transporters may have multiple roles during light stress, which make them very important targets for plant breeding.

## 15.1 INTRODUCTION

In nature, plants frequently experience a wide range of stresses. An investigation of functional plasticity is necessary to understand responses to environmental conditions, the distribution of the species, and to predict the dynamics of vegetation under the global changes of climate. The indices of photosynthetic apparatus, such as the composition, the content, and the ratio of pigments are considered to be the most informative to characterize the functional plant state (Lubimenko 1963, Zalenskii 1977, Maslova and Popova 1993, Pyankov and Mokronosov 1993, Bazzaz 1996, Dymova and Golovko 2007, Golovko et al. 2007).

Chlorophylls and carotenoids are required for photosynthesis. Chlorophylls are necessary for the capture of light energy and as primary electron donors. Carotenoids play crucial roles in both light harvesting and energy dissipation for the protection of photosynthetic structures. So far, the spectral characteristics and the biosynthesis of photosynthetic pigments have been studied, the concept of the antenna complex and the reaction centers has been developed, and the fundamental mechanisms of photosynthesis have been revealed. At the same time, the diversity and ecological conditions of habitation of plant species make the investigation of the pigments' role in the stability and regulation of the photosynthetic apparatus activity the topical problem. A qualitative content and a quantitative composition of pigments and their ratio changes are the important and responsive characteristics of the physiological state of plants and their photosynthetic apparatus. However, current information about the pigment system of plants from different botanical and geographical zones is rare and contradictory (Lukyanova et al. 1986, Popova et al. 1989, Kornushenko and Solovjova 1992, Maslova and Popova 1993, Golovko et al. 2007).

Northeast European Russia is a unique region in continental Europe. Here, plant growth is restricted by lack of warmth, short vegetative period, and poor soils. Photosynthetic apparatus, including pigment complex, prove additional stress in these severe conditions.

We advance the idea of increasing the role of pigments in tolerance and in the productivity of photosynthesis of plants in the taiga cold climate environments. The results presented in this chapter provide proof for this idea.

15.2 PHOTOSYNTHETIC PIGMENT CONTENTS IN NORTHERN PLANTS

We studied the pigment complex of more than 100 plant species inhabiting three different sites in the European North-East of Russia: (1) the Subpolar Ural Mountains (65°22' N, 60°46' E), (2) the South Tyman (62°45' N, 55°49' E), and (3) the Middle Vychegda basin (61°38' N, 50°43' E).

The main climatic traits of these regions are shown in Table 15.1. The Subpolar Ural Mountains (the extremely north taiga subzone) is characterized by the most severe climate and a short vegetative period. The climate in the Middle Vychegda (the middle taiga subzone) is warmer, but the growing season in this region does not exceed 100–110 days. The mean annual air temperature only slightly exceeds 1°C. Though the region of the South Tyman belongs to the middle taiga subzone, it differs from the Middle Vychegda by the temperature regime and the duration of the vegetative period.

The list of examined plant species in each region is shown in Table 15.2. All 121 plant species have been investigated and most of them are boreal herbaceous plants and reflect the structure of the floristic complexes in the studied regions.

Leaf samples for pigment analyses were collected from 20 to 30 plants of each species from the beginning–middle of July (2004–2008). Analyses were carried out on mature healthy current-year leaves (herbs) or current-year shoots (*Empetrum nigrum* and *E. hermaphroditum*, *Lycopodium clavatum* and *L. annotinum*, *Diphasium complanatum*). The second-year needles were collected from evergreen conifers (*Abies sibirica*, *Juniperus communis*, *Picea obovata*, *Pinus sibirica*). The majority of herbaceous plants flowered during the sampling.

Leaf chlorophyll (Chl) and carotenoid (Car) contents were measured by UV-1700 spectrophotometer (“Shimadzu”, Japan) in acetone extracts at 662 (Chl *a*), 644 (Chl *b*), and 470 nm (total Car). The chlorophyll portion in light-harvesting chlorophyll (LHC) (LHC-Chl) was calculated, assuming that the total Chl *b* was located in LHC and the Chl *a/b* ratio in this complex was equal to 1.2 (Lichtenthaler 1987). Separations and quantifications of Car were done by reversed-phase high-performance liquid chromatography (HPLC) according to Gilmore and Yamamoto (1991).

15.2.1 PIGMENT COMPLEX OF THE SUBPOLAR URAL MOUNTAINS PLANTS

The differences in the accumulation of photosynthetic pigments were revealed between species (Figure 15.1). The concentration of Chl and Car varied in the ranges of 1.5–14 and 0.5–5 mg/g dry weight (DW), respectively. The legume plants (*Astragalus norvegicus*, *A. frigidus*, *Hedysarum arcticum*)

TABLE 15.1  
Mean Climatic Traits of Different Places in the European North-East

| Traits                                                   | Subpolar Ural Mountains | The South Tyman | The Middle Vychegda Basin |
|----------------------------------------------------------|-------------------------|-----------------|---------------------------|
| Mean annual air temperature, °C                          | −4.8                    | −1.5            | +1                        |
| Mean July air temperature, °C                            | +13                     | +15             | +17                       |
| Total temperature above +5°C                             | 1070                    | 1550            | 1800                      |
| The duration of growing season (above +5°C), days        | 105–110                 | 133             | 150                       |
| The duration of active growth period (above +10°C), days | 60–70                   | 80–90           | 100–110                   |
| Mean annual precipitation, mm                            | 600–685                 | 660–750         | 650–765                   |

Notes: Life-form groups: H—herb, T—tree, SH—shrub; C-M—club-moss; latitudinal groups: A—arctic, AA—arctic and alpine, B—boreal species; P—prairie, R—rocky species. Latin names of species given by Cherepanov (1995). Species presented with note of its life form and geographical status.

FIGURE 15.1 Chlorophyll (dark symbols) and carotenoid (light symbols) contents in the leaves of the Subpolar Ural Mountains plants. For species names view according to the numbers in Table 15.2.

were characterized by a higher green pigment content. Conifer (*Larix sibirica*), dwarf shrubs (*Empetrum hermaphroditum*, *Phyllodoce caerulea*, *Ledum decumbens*, *Vaccinium uliginosum*), club mosses (*Lycopodium clavatum* and *L. annotinum*), and herbs (*Diapensia lapponica*) had a very low Chl content. In the leaves of more than 60% of the examined species, the content of green pigments consisted of 3–6 mg/g DW. These concentrations can be considered relatively low.

The Chl *a/b* ratio varied from 2 to 3.5, but it was higher (3.8–4.0) in *Bartsia alpina*, *Salix dasyclados*, *Astragalus frigidus*, and *Hedysarum arcticum*. In most of the species, Chl belonging to the light-harvesting complex (LHC-Chl) consisted of 55%–65% of the total. In *B. alpina*, *A. frigidus*, *H. arcticum*, and woody *S. dasyclados* leaves, the LHC-Chl values were the lowest (43%–45%).

**FIGURE 15.2** The relationship between chlorophylls and carotenoids in the leaves of the Subpolar Ural Mountains (A), the South Tyman (B), and the Middle Vychegda (C) plants.

The leaves of *Arctous alpine* and *Pyrola rotundifolia* were characterized by the highest LHC-Chl level (70%–80%).

There are positive correlations found between the yellow and the green pigment concentrations (Figure 15.2A). The majority of the examined species had the Car content of 0.9–1.7 mg/g DW. *Diapensia lapponica*, *Arctous alpine*, *Phyllodoce caerulea*, *Achillea nigrescens*, *Lycopodium clavatum*, *L. annotinum*, and *Vaccinium uliginosum* were distinguished by a low accumulation of yellow pigments (0.6–0.8 mg/g DW). Some of the legumes (*Hedysarum arcticum*, *Astragalus frigidus*) and *Pedicularis verticillata* had a high Car content, 4.5 mg/g DW. The Chl/Car ratios were 2.5–3.0 in most of the species, but these values were higher (4–5) in *Carex aquatilis*, *Calamagrostis purpurea*, and *Arctous alpine*.

Plants with different Chl and Car accumulation levels were revealed among the groups that differed by life forms (herbs, ferns, trees and dwarf shrubs, and mosses). In the herbaceous plants group, there were species with an extremely low (*Achillea nigrescens*) and a high (*Astragalus frigidus*) content of photosynthetic pigments. However, overall perennial herbaceous plants, especially leguminous, contained more Chl and Car than trees and dwarf shrubs (Figure 15.3A). Among shrubs, *Salix* species, *Betula nana* and *Pentaphylloides fruticosa*, had a comparatively high Chl content (2–5 mg/g DW). Ferns had the same Chl level. Mosses were characterized by the lowest pigment accumulation.

A comparison of plants from different latitudinal groups (Figure 15.4A) showed that arctic, arctic-alpine, and hypo-arctic species contained similar amounts of photosynthetic pigments as that of the boreal species. In the arctic and arctic-alpine species, the ratio of green and yellow pigments was lower (2.9) as compared to boreal species (3.2). This indicates a relatively high Car in the pool of photosynthetic pigments of arctic and arctic-alpine species on the Subpolar Ural Mountains.

In general, the study carried out on the Subpolar Ural Mountains showed that the contents of the photosynthetic pigments depend more on the plant species and its life form, whereas the Chl/Car ratio depends on the geographical group. It should be noted that the pigment complex was characterized by a relatively low Chl content.

### 15.2.2 PIGMENT COMPLEX OF SOUTH TYMAN PLANTS

Among the 47 species of South Tyman plants examined, 74% belong to the boreal latitudinal group. The other species are included in the arctic, the arctic-alpine, and the hypo-arctic groups. These plant species were mostly found in rocky floristic complexes.

**FIGURE 15.3** Chlorophyll (dark symbols) and carotenoid (light symbols) contents in the leaves of the Subpolar Ural Mountains (A), the South Tyman (B), the Middle Vychegda (C). Life-form groups: H—herbs, T—trees, SH—shrubs, F—ferns, and C-M—club-mosses.

**FIGURE 15.4** Chlorophyll (dark symbols) and carotenoid (light symbols) contents in the leaves of the Subpolar Ural Mountains (A), the South Tyman (B), and the Middle Vychegda (C). Latitudinal groups: B—boreal, A—hypo-arctic, AA—arctic and alpine.

The South Tyman plants differed appreciably by the green pigment content. The Chl concentrations of these plant species varied from 1.5 to 14 mg/g DW (Figure 15.5). Conifer (*Pinus sibirica*), shrubs (*Vaccinium uliginosum*) and some herbs (*Pedicularis verticillata*, *Dendranthema zawadskii*) had comparatively low pigment content. Several species, including Trilliaceae (*Paris quadrifolia*), Orchidaceae (*Cypripedium calceolus*), Asteraceae (*Crepis sibirica*, *Petasites radiatus*), Rosaceae (*Geum rivale*), and Fabaceae (*Vicia cracca* and *V. sylvatica*, *Lathyrus pratensis*) were characterized by high Chl and Car contents.

The Chl and Car ratios were 2.4–3.1 in most of these species. These values were higher (3.6–3.9) in *Gymnadenia conopsea*, *Pedicularis verticillata*, and *Thymus taljievii* plants. The majority of species had LHC-Chl levels equal to 50%–65% of total Chl. Among the examined species, only in the leaves of *Pinguicula vulgaris*, LHC-Chl was 75%. The high percentage of Chl in LHC can increase the absorption of light energy and compensate a relatively low level of the green pigment in *Pinguicula* leaves. It should be noted that this plant was characterized by various types of nutrient deficiencies. It is an insectivorous plant.

As for the Subpolar Ural Mountains plants, a strong positive relationship between the content of the green and the yellow pigments with that of the South Tyman plants was revealed (Figure 15.2B).

**FIGURE 15.5** Chlorophyll (dark symbols) and carotenoid (light symbols) contents in the leaves of the South Tyman plants. For species names see according to the numbers in Table 15.2.

Although the Car concentration varied strongly, from 0.3 to 2.5 mg/g DW, the ratio Chl/Car was rather similar for most of the plants, i.e., equal to 4–5.

The herbaceous plants were characterized by higher Chl and Car contents than ferns, trees, and shrubs. The mosses had the lowest concentration of photosynthetic pigments (Figure 15.3B). The comparison of the plants from different latitudinal groups showed that arctic and hypo-arctic species accumulated lower amounts of pigment than the boreal plants (Figure 15.4B). Thus, arctic-alpine species were characterized by a low value of Chl/Car ratio (3.7) as compared to boreal plants (4.1).

### 15.2.3 PIGMENT COMPLEX OF MEADOW AND FOREST PLANTS IN THE MIDDLE VYCHEGDA BASIN

Forty-seven species inhabiting the meadows and forests were studied. Our data showed (Figure 15.6A) that the leaf Chl content was relatively high (more than 4–5 mg/g DW) in a majority of these plants. In *Paris quadrifolia*, *Calla palustris*, and *Aconitum septentrionale*, the Chl content was about 14 mg/g DW. The LHC-Chl level was varied significantly, from 44% to 74%. More LHC-Chl was accumulated in the forest herbs compared to the rest of the other species examined in this area. Although the species were distinguished by the Chl and Car concentrations, there was a positive correlation between the green and the yellow pigment accumulations. The content of the yellow pigments was four- to eightfold less than that of the green pigments. *Lycopodium clavatum*, *Vaccinium vitis-ideae*, *V. myrtillus*, *Abies sibirica*, and *Pinus sibirica* contained a comparatively small amount of Car (0.4–0.5 mg/g DW). But, *Thalictrum simplex*, *Alisma plantago-aquatica*, and *Aconitum septentrionale* accumulated five times more yellow pigments than green pigments.

In the Middle Vycheгда flora, like the other regions, it was observed that the herbs were characterized by the highest accumulation of photosynthetic pigments (Figure 15.3C). The Chl and Car contents were 1.5–2-fold lower in trees and mosses. The comparison of the plants from different

**FIGURE 15.6** Chlorophylls (dark symbols) and carotenoids (light symbols) content in the leaves of the Middle Vychegda basin plants. For species names see according to the numbers in Table 15.2.

latitudinal groups showed that hypo-arctic species accumulated 1.3 times lower photosynthetic pigments than the boreal species (Figure 15.4C).

So, our data have shown that most of the examined plants from the Subpolar Ural Mountains and the South Tyman regions were characterized by a relatively higher content of the yellow pigments (Figure 15.7). The herbs accumulated 2–3 times more pigments than trees and mosses. Photosynthetic pigment pools in the leaves of the plants inhabited in the Middle Vychegda basin were larger as compared to plants on the Subpolar Ural Mountains.

**FIGURE 15.7** The ratio of chlorophylls to carotenoids in the leaves of the plants from different regions.

15.3 SEASONAL CHANGES IN LEAF PIGMENT CONTENTS AND XANTHOPHYLLS CYCLE ACTIVITY IN EVERGREEN CONIFEROUS SPECIES

The evergreen conifers are the main woody species in the taiga zone and they occupy about 80% of the woodland of the Komi Republic (Virgin spruce forests ... 2006). The retention and maintenance of the pigment complex's functional activity in the annual cycle are important for the evergreen species of the boreal zone, which adapt to the long-term cold period. Low-temperature conditions during winter can inhibit CO<sub>2</sub>-exchange and carbon photosynthetic metabolism, but low temperatures do not affect the ability of chlorophyll to absorb light. Thus, winter conditions can cause a severe imbalance between light absorption and its utilization via photosynthesis. In such conditions, plants use photoprotective mechanisms to deal with the excess light absorbed by chlorophyll. The key mechanism includes the xanthophyll cycle-dependent thermal energy dissipation of excess light within the light-harvesting complexes. It is shown that the de-epoxidation of the xanthophyll cycle pigments was significantly higher in evergreen plants during winter (Garcia-Plazaola et al. 2003, Verhoeven et al. 2005).

We studied seasonal changes in the photosynthetic pigment content in three conifers: *Abies sibirica*, *Picea obovata*, and *Juniperus communis*. The concentrations of Chl and Car were relatively low, 2.4–4.3 × 0.45–1.0 mg/g DW, respectively (Figure 15.8). In winter, the reduction of the photosynthetic pigment pool was maximal in *Juniperus communis* needles. In *Picea obovata* and *Abies sibirica*, the pool of green pigments is more stable during the year. Essential seasonal differences in the chlorophyll *a/b*, the Chl, and the Car ratio were not found (Table 15.3). In spring and summer, all species had a tendency to a higher LHC-Chl level.

**FIGURE 15.8** Seasonal changes in the chlorophyll (dark symbols) and carotenoid (light symbols) contents in *Picea abies* (A), *Abies sibirica* (B), and *Juniperus communis* (C) needles. (From Yatsco, Y.N. et al., *Botan. Z.*, 94(12), 1812, 2009.)

Note: LHC-Chl—Chlorophyll belonging to light-harvesting complex, *n* = 5.

**FIGURE 15.9** Seasonal changes in the carotenoid composition (as a percent of total carotenoid content) in *Picea obovata* (A), *Abies sibirica* (B), and *Juniperus communis* (C) needles. 1—zeaxanthin, 2—neoxanthin, 3—antheraxanthin, 4—lutein, 5—violaxanthin, and 6— $\beta$ -carotene.

The carotenoid composition for all species was presented mainly by xanthophylls (90%) during the whole year (Figure 15.9). The portion of  $\beta$ -carotene consisted of 10%–20% of Car content. Among the xanthophylls, the level of lutein was the highest and reached 70%. Neoxanthin (7%–10%) and violaxanthin (3%–15%) were presented constantly in relatively small amounts. In the studied plants, violaxanthin was the predominant component of the xanthophylls cycle, whereas two other components of the xanthophyll cycle (zeaxanthin and antheraxanthin), were noted mainly during winter and spring, and none identified in summer.

The analyses of the seasonal changes of the individual carotenoids showed an increase of  $\beta$ -carotene and violaxanthin levels in summer, whereas antheraxanthin and zeaxanthin were practically absent at this time. A low amount of antheraxanthin was found in autumn. Antheraxanthin levels in the carotenoid pools of *Picea obovata* and *Abies sibirica* needles were 7%–8% in winter and at the beginning of spring. There was 15% (of total carotenoid content) of antheraxanthin in *Juniperus communis* in winter. The level of antheraxanthin (up to 5%) was preserved in *Juniperus* needles until May. Zeaxanthin appeared in the beginning of winter, and its level increased in spring. Zeaxanthin disappeared fully in summer. The same seasonal pattern of zeaxanthin was revealed for *Picea obovata* and *Abies sibirica*.

The de-epoxidation state (DEPS) was characterized by the ratio between de-epoxidized and the epoxidized forms of the xanthophyll cycle components. According to Schindler and Lichtenthaler (1996), DEPS can be estimated from the equation,  $DEPS = (zeaxanthin + 0.5 \text{ antheraxanthin}) / (zeaxanthin + antheraxanthin + violaxanthin)$ . Evaluation of DEPS showed that the de-epoxidation of the xanthophyll cycle pigments was high in all the examined species in winter and the early spring (Table 15.4). The DEPS values decreased 2–3 times in May. The de-epoxidation of the xanthophyll cycle pigments was almost completely suppressed in summer (July). The repair of de-epoxidation reaction (by 30%) was observed in *Picea obovata* needles in autumn (September), in the other two species—in December. It should be noted that for this period, *Picea obovata* was already characterized by maximum DEPS values.

We noted already, that *Picea obovata* needles were distinguished by the greatest stability of the pigment pool during the year among the studied species. In *Abies sibirica* and *Juniperus communis* needles, a portion of the pigments in winter and spring had been destroyed. Several investigators have reported the loss of chlorophyll in the needles of the conifers, in winter (Ottander et al. 1995, Enslinger et al. 2004, Martz et al. 2007). Information about pigment complex preservation was

given by Lukyanova et al. (1986). It seems that the different opinions about the character of the seasonal changes in pigment composition in conifers depend on the species traits and the climatic conditions of the habitats. Winter and spring loss of pigment was repaired in summer and autumn. The structural and functional changes of mesophyll at the initial stage of the hardening in autumn are important for the preservation of the photosynthetic apparatus. In the needles of *Picea obovata*, the disappearance of the starch grains, the change of form, size and localization of the chloroplasts are shown (Ladanova and Tuzhilkina 1992). The absorption of light energy was reduced due to the relocation of chloroplasts to the central part of the cell and grouping around the nucleus. This fact can be regarded as the adaptive reaction that is directed to the reduction of light absorption in winter and spring when the photosynthetic consumption of excitation energy is blocked.

**15.4 SUMMARY AND CONCLUSIONS**

The contents and the ratio of photosynthetic pigments in plant leaves, growing in the Subpolar Ural Mountains, the South Tyman, and the Middle Vychegda basin, were investigated. We found that the level of the carotenoid accumulation in the plant leaves from all the studied regions correlated closely with the chlorophyll content. In comparison of our data with the results reported by Maslova and Popova (1993) for other regions, it was found that the Subpolar Ural Mountains plants are closer to the alpine plants of the East Pamirs, the South Tyman plants—to the arctic plants of Taimir, and the middle Vychegda plants—to the species of the temperate zone on the Chl/Car index.

Carotenoids exhibit both light-harvesting and photoprotective functions (Demmig-Adams 1990, Rmiki et al. 1999, Cuttriss and Pogson 2004). Therefore, the relatively high level of the yellow pigments in the leaves of the Northern plants, especially arctic species, can be regarded as the adaptive reaction that is directed to an increase in the stability of the pigment complex and to prevent its photodynamic destruction in the cold climate. The pigment complex of the species from the middle taiga subzone was characterized by a higher Chl/Car ratio and the lower yellow pigment contents were in contrast to the Subpolar Ural Mountains plants. This confirms the important role of the carotenoids in the stability of the pigment complex of the extremely north taiga subzone plants. It should be noted that carotenoids not only have a protective role, but also absorb light in the near ultraviolet (UV) as well as the visible region. Carotenoids are bound, together with Chl, to proteins and participate in light harvesting. As components of the antenna complex, they provide more effective use of solar radiation during the short north summer.

Pigments, especially carotenoids, perform an essential photoprotective role in evergreen conifers' photosynthetic apparatus. Preservation and the long-term functioning of the photosynthetic apparatus allow conifers to occupy the temperate and subarctic Northern hemisphere, where freezing temperatures occur regularly and cold acclimation processes are essential to enable plants to withstand periods of very low temperatures (Levitt 1980). Conifers retain their needles for several

years and so their photosynthetic apparatus must survive severe freezing periods, often combined with high light, especially in early spring. The interaction of light and low temperature can result in the photo-inhibition of photosynthesis in nature (Martin et al. 1978, Ottander and Oquist 1991). Our data showed that the pool of carotenoids in conifers during the vegetative period consists of  $\beta$ -carotene, lutein, and violaxanthin. In pigment apparatus of the conifers, the high level of lutein remained fairly constant during the year. It is possible that the lutein content is related to the structural role of this xanthophyll, which is the integral component of the peripheral unit of LHC II, and on its possible antioxidant function (Kuhlbrandt et al. 1994). Accumulation of antheraxanthin and zeaxanthin in the carotenoid spectrum was observed in winter and at the beginning of spring under freezing stress combined simultaneously with high light. According to (Demmig-Adams 1990, Eskling et al. 1997) zeaxanthin is the exclusive xanthophyll that is accumulated under excess light by deep oxidation of the existing violaxanthin in the xanthophyll cycle. It is widely thought to play a photoprotective role by the dissipation of excessive light energy as heat (Niyogi 1999). Previous research has shown that zeaxanthin can quench the  $^1\text{Chl}^*$  state directly through the process of non-photochemical quenching (NPQ) (Muller et al. 2001). Antheraxanthin, another xanthophyll, has a similar function of photoprotection with zeaxanthin, and it can replace zeaxanthin in the absence of zeaxanthin (Goss et al. 1998). So, our data show that the primary photoprotective mechanism of the three evergreen conifers growing in the cold climate is the increase in the degree of the de-epoxidation state of the xanthophyll cycle and the accumulation of zeaxanthin. It provides a harmless dissipation of excess excitation energy in the photochemical system. Lutein, another xanthophyll, is important for photoprotection in conifers too.

As a whole, information on pigment apparatus of different botanical and ecological groups of Northern plants was completed and summarized. The significant differentiation of species on the green and the yellow pigment contents was found. An increase of the relative content of carotenoids in row boreal—hypo-arctic—arcto-alpine species was found. New data on the light-dependent changes of xanthophyll cycle pigments (violaxanthin, antheraxanthin, and zeaxanthin) on the Northern conifers are found. The role of carotenoids in the tolerance of photosynthetic apparatus and protection against photo-oxidative damage in leaves of plants from the Northern regions is shown. It was concluded that the relatively high content of carotenoids plays a major role in the stability of the photosynthetic apparatus in cold climatic conditions. The results obtained extend our knowledge about mechanisms of adaptation of pigment apparatus and photosynthetic function realization in plants under cold climate environments.

## 16.1 INTRODUCTION

Since the emergence of life on Earth, the food chains depend on the use of solar energy by photosynthetic organisms. One characteristic feature of these organisms resides in their global lack of mobility, even though microalgae can move in the water column. Consequently, this type of organisms cannot run away from the alterations in their biotic and/or abiotic environments, including deficiencies or excesses of light or nutrients. To cope with these alterations, photosynthetic cells activate different types of defense mechanisms, including reorientations of the plastid metabolism. Because the rapidity and efficiency of the responses differ among species or even plant cultivars, this aptitude to adapt to unfavorable conditions constitutes a major factor for their survival (Külheim et al. 2002). For instance, sun-grown leaves exhibit a greater ability to activate photoprotective mechanisms, such as the xanthophyll cycle, than shade-grown plants when both types of plants are exposed to high light (Demmig-Adams and Adams 1994, 1995, 2006).

In this chapter, that is an update of the data presented in the second edition of the *Handbook of Plant and Crop Stress* (Rmiki et al. 1999), we have reviewed the data dealing with the changes in the carotenoid (Car) and apoCar (ApoCar) metabolisms in algae and plants as a response to stress.

## 16.2 PROPERTIES OF CAROTENOIDS IN PHOTOSYNTHETIC ORGANISMS

Cars are C40-polyisoprenic compounds characterized by a large number of conjugated double bonds ( $n > 7$ ). More than 600 Cars have been identified to date and several new ones are reported annually. Conjugated double bonds allow Cars to absorb light in the near-ultraviolet as well as in the visible region. In photosynthetic organisms, Cars are bound, together with chlorophylls (Chls), to proteins and participate in light harvesting and in energy transfer to the photosynthetic reaction centers. This last process resides on a very efficient singlet–singlet energy transfer from Cars to Chls and needs a precise arrangement of pigment molecules in the light-harvesting complexes (LHCs). Cars are also recognized to be essential for the survival of illuminated plants, since their numerous conjugated double bonds are able to quench the Chl triplet state and also to scavenge singlet oxygen and the other reactive oxygen species (ROS), which are abundantly produced during photoinhibition. This photoprotective function is generally achieved *via* triplet–triplet energy transfer. In addition to these well-established functions, Cars of higher plant plastids might play important structural roles in stabilizing the lipid phase of the thylakoid membranes through modification of the membrane fluidity (for a review, see Havaux 1998).

## 16.3 DIVERSITY OF STRESSES ON CAROTENOID BIOSYNTHESIS

Various factors (e.g., nutrient deficiency, excess light, drought, and chilling) are known to have consequences on the photosynthetic apparatus, and photoinhibition may be often observed under these environmental conditions. Actually, in their natural environment, plants are constantly confronted with reconciling an excessive energy supply with the demands of the photosynthetic carbon reduction cycle for the products of electron transport, ATP and NADPH (Osmond 1981). When light absorption by LHC exceeds both the capacity to use the photosynthetic NADPH and ATP for carbohydrate synthesis and the capacity of energy dissipation mechanisms, photosynthesis is progressively inhibited (i.e., photoinhibition phenomenon). This means that even low light levels may become excessive if combined with chilling and then may result in photoinhibition in crops or in algae. The consequences at the Car level of any stress may be multiple (for a review, see Young and Britton 1990).

To cope with the absorption of excessive light and its consequences, the photosynthetic organisms have evolved a series of short-term (10–30 min) and long-term photoprotective mechanisms (Horton and Ruban 1992). Among these mechanisms, the thermal dissipation of excess absorbed light energy at the photosystem (PS) II, the so-called nonphotochemical quenching (NPQ), is believed to play a key role in regulating the light harvesting and in the prevention of photooxidative damages.

## 16.4 THE VIOLAXANTHIN CYCLE: A SHORT-TERM PHOTOPROTECTIVE MECHANISM

Basically, the photosynthetic apparatus constitutes an optimized biological device to store the energy of light into molecules. Because the photosynthetic apparatus manipulates oxygen and light, the interaction between singlet Chl molecules and triplet oxygen is strictly avoided by a variety of photoprotective Cars bound to the proteins of the photosynthetic apparatus (Frank and Cogdell 1996), because the interaction yields to the formation of singlet oxygen, which can damage proteins, pigments, and lipids in the photosynthetic apparatus (Niyogi 1999, Asada 2006). When the capacity to harvest the light energy is higher than the capacity to use it, the actual set of photoprotective Cars is no longer able to efficiently dissipate the absorbed energy and the excess of absorbed light should be dissipated through other pathways. Early research identified a dissipation process induced by the lowering of the lumen pH, a condition triggered by high-light conditions (for reviews, see Krause and Weis 1991, Demmig-Adams and Adams 1996, Rmiki et al. 1999). A connection was subsequently made between energy dissipation and the Cars of the xanthophyll cycle (Demmig et al. 1987, Demmig-Adams 1990). The role of zeaxanthin (Zea) as a general antioxidant has been confirmed using the *npq2* mutant that accumulates Zea (Niyogi et al. 1998) and shows a higher NPQ level than in the wild type (Niyogi et al. 1998, Havaux et al. 2000, Kalituho et al. 2007). Studies of *Arabidopsis* plants containing nearly three times the amount of xanthophyll cycle Cars present in the wild type have given further details on the antioxidant function of these pigment conversions involving their binding to proteins of the LHC family (Johnson et al. 2007).

With the development of a high-pH gradient across the thylakoids, two-steps mono de-epoxidation reactions of the Violaxanthin (Vio) into Zea with antheraxanthin (Ant) as an intermediate are catalyzed by the Vio de-epoxidase (VDE) (EC 1.10.99.3) (Figure 16.1). The Vio molecules are regenerated through two light-independent epoxidation steps that are catalyzed by the Zea epoxidase (ZEP) (EC 1.14.13.90). The transformation of Vio to Zea proceeds in about 10–30 min (Sierfermann-Harms 1977) whereas the conversion of Zea to Vio is 5–10 times slower (Härtel et al. 1996, Marin et al. 1996). Both VDE and ZEP have a similar basic tertiary structure, maybe because they share a common Ant substrate and belong to the lipocalin family of proteins (Bugos et al. 1998; Hieber et al. 2000, 2002, Wang et al. 2008; for a review, see Jahns et al. 2009). Lipocalins are characterized by a similar tertiary structure and similar functions (Grzyb et al. 2006). These enzymes are supposed to contain eight antiparallel  $\beta$ -sheets and three highly conserved short consensus repeat motifs (Flower et al. 2000). The motif I is composed of the first of the eight  $\beta$ -sheets and a short fragment of the preceding  $\alpha$ -helix. Motif II is composed of the loop between  $\beta$ -sheets number 6 and 7 and parts of the end of  $\beta$ -sheet number 6 and the beginning of  $\beta$ -sheets number 7. The motif III is composed of the end of  $\beta$ -sheet number 8 and part of the C-terminal  $\alpha$ -helix, including the loop between both fragments. VDE and ZEP are conserved in two and only one short consensus repeat motif, respectively (Akerstrom et al. 2000), and differ by the number of amino acid residues between the motif I and II (Bugos et al. 1998). The 3D structure of lipocalins is characterized by the deep conic hollow, formed by the  $\beta$ -sheets. The deep conic hollow is necessary for substrate binding (Newcomer et al. 1984, Holden et al. 1987).

### 16.4.1 VIOLAXANTHIN DE-EPOXIDASE

The first cDNA sequence of VDE was obtained from romaine lettuce (Bugos and Yamamoto, 1996). The VDE sequences homologous to VDE from plants were identified in the genome of diatoms *Thalassiosira pseudonana* and *Phaeodactylum tricornutum* (Bacillariophyceae). No VDE sequence was found in the red algae genome library even if some red seaweeds are able to produce Ant (Rmiki et al. 1996) or Vio (Coesel et al. 2008). For instance, *Gracilaria gracilis* and *G. multipartita* are devoid of Vio, and a xanthophyll cycle restricted to the interconversions of Ant to Zea was observed (Rmiki et al. 1996; Garcia-Plazaola et al. 2007). A sequence constituting a novel gene,

**FIGURE 16.1** The different xanthophyll cycles. Under stress conditions, Vio, Ddx, or Lut-epoxide are de-epoxidized into Zea, Dtx, or Lut, respectively. After suppression of the stress conditions, the de-epoxidated xanthophylls are epoxidized.

named VDE-related or VDR, was identified in the genome of *Chlamydomonas reinhardtii* as sharing a low sequence similarity with *Arabidopsis thaliana* VDE. VDE-related homologs were found in higher plants and in two diatom genomes (Coesel et al. 2008).

VDE is a nucleus-encoded protein. The plastid import mechanism involves a bipartite transit peptide located at the N-terminal of the preprotein sequence. The first part of the transit peptide allows the targeting of the protein to the chloroplast stroma, whereas the second part drives the thylakoid-targeting. These results confirm the location of mature VDE protein (43 kDa) in the lumen of the thylakoids (Bugos et al. 1999; for a review, see Rmiki et al. 1999). Depending on the pH, the mature VDE, that is present in very small amounts, occurs either as a soluble protein (neutral pH) or as a tightly bound protein at the lumenal surface of the thylakoid when the lumen acidifies (Eskling et al. 1997). The mutant *npq1* is defective in VDE (Niyogi et al. 1998).

The comparison of the VDE sequences showed similarities at two domains. The first one is a cystein-rich N-terminal domain, probably organized in  $\alpha$ -helices, whereas the second one is a glutamic acid-rich C-terminal domain, composed of long  $\alpha$ -helices (Hieber et al. 2000). This last domain would serve for the pH-dependent binding. Actually, when it is partially protonated, the binding of VDE protein to the thylakoid membrane is increased (Hieber et al. 2002, Coesel et al. 2008). In VDE, the lipocalin hollow fits with the length of Vio molecule and would explain why there is strict specificity of the enzyme for 3-OH, 5-6-epoxy Cars in configuration 3*R*, 5*S*, and 6*R* (Yamamoto 1979, Grotz et al. 1999).

VDE requires ascorbate, under its acidic form, as a cosubstrate (Yamamoto 1979, Eskling et al. 1997, Jahns et al. 2009). The protonated ascorbate content of the lumen is an endogenous proton and electron donor and it has been shown to activate the VDE activity *in vivo* in *Arabidopsis* (Yamamoto 1979, Neubauer and Yamamoto 1994, Müller-Moulé et al. 2002). The optimum ascorbate concentration for VDE activity is pH-dependent, that is, at pH 4.5–5.5, the enzyme becomes saturated at 10–20 mM, whereas at pH 6, the saturation level is not reached before 100 mM (Bratt et al. 1995). Ascorbate, reduced in the stroma by the glutathione cycle, which consumes NADPH and glutathione, may cross the thylakoid membrane and regulate the activity of PSII (Foyer et al. 1989). The existence of a membrane transporter for negatively charged ascorbate in exchange for dehydroascorbate was postulated (Bratt et al. 1995, Eskling et al. 1997).

The VDE activity is reversibly inhibited by dithiothreitol through the reduction of the disulfide bonds in the enzyme if the inhibitor is added at pH 5.2–5.7 (Yamamoto and Kamite 1972, Bugos et al. 1999, Coesel et al. 2008).

#### 16.4.2 ZEAXANTHIN EPOXIDASE

The first ZEP cDNA, originally named as ABA2, was isolated from tobacco (*Nicotiana glauca*) using the insertional mutagenesis technique (Marin et al. 1996, Audran et al. 1998, Wang et al. 2008). Later, this cDNA was used to allow the isolation of other ZEP sequences from other dicotyledon plants like pepper (*Capsicum annuum*), tomato (*Lycopersicon esculentum*), *Arabidopsis*, and apricot (*Prunus armeniaca*) (Hieber et al. 2000), monocotyledon plants, green algae, diatoms, and *Tetrahymena thermophila*—a ciliate organism (Coesel et al. 2008). The mutant *npq2* of *A. thaliana* is devoid in ZEP (Niyogi et al. 1998).

ZEP preprotein contains a chloroplast transit peptide that is cleaved during the targeting into the chloroplast stroma (Audran et al. 1998). The comparison of ZEP mature protein sequences indicated that, in addition to the lipocalin typical domain, the sequences also share a flavoprotein monooxygenase consensus domain similar to the prokaryotic aromatic-substrate monooxygenases (Hieber et al. 2000). The sequence has a phosphopeptide-binding domain, which could be involved in protein–protein interactions (Coesel et al. 2008, Wang et al. 2008). The ZEP enzyme, that is active at the stromal side of thylakoids, with an optimum pH around 7.5, requires FAD, O<sub>2</sub>, NADPH, and “ferredoxin-like” reductives as cosubstrates for the epoxidation reaction (Hager 1975, Siefermann and Yamamoto 1975a, Siefermann and Yamamoto 1975b, Siefermann and Yamamoto 1975,

Wang et al. 2008). So far, no ZEP protein could be purified from organisms. Actually, the regulation of ZEP activity is not well understood but it has been shown that downregulation may occur under extreme photooxidative stress conditions in the short- (Jahns 1995, Reinhold et al. 2008) or long term (Adams et al. 2002).

Even if the ZEP tomato gene was expressed preferentially in chlorophyllous tissue, the ZEP transcripts were also detected in flowers, roots, and fruits (Wang et al. 2008). In the nonchlorophyllous tissues of *Arabidopsis*, Zea epoxidation is involved in the abscissic acid biosynthesis (Audran et al. 2001). Diatoms that do not produce this phytohormone also use ZEP to synthesize fucoxanthin, their major light-harvesting Car, is realized at the expense of Vio (Lohr and Wilhelm 2001).

### 16.4.3 SECOND XANTHOPHYLL CYCLE IN HIGHER PLANTS: THE LUTEIN-5,6-EPOXIDE CYCLE

In maturing tomato fruit (*Lycopersicum esculentum* Mill. cv Moneymaker), besides a typical Vio cycle, a second cycle of lesser amplitude was observed between Lutein (Lut) and Lut monoepoxide (Rabinowitch et al. 1975) (Figure 16.1). More recently, operation of this new type of xanthophyll cycle was observed in two parasitic angiosperms, that are, *Cuscuta reflexa* (Bungard et al. 1999) and *Amyema miquelii* (Matsubara et al. 2001) but not in the roots of other parasitic organisms such as *Arceuthobium* sp. and *Phoradendron* sp. (Ladygin 2008). This cycle was later found in maturing green fruits of tomato and in leaves of eight *Quercus* species (Garcia-Plazaola et al. 2002a). A de-epoxidase is involved in this cycle allowing, under a strong light, the conversion of Lut-5,6-epoxide into Lut, whereas under low light, the reverse reaction goes back but at a very slow rate. One important question that remains is to determine which enzymes are involved in the Lut-Lut-epoxide cycle. In the one hand, no enzyme implicated in the Lut-5,6-epoxide cycle was clearly identified (Giuliano et al. 2008) but in the other hand, VDE could catalyze, in addition to the Vio-de-epoxidation, the conversion of Lut-5,6-epoxide into Lut *in vitro* (Grotz et al. 1999, Goss 2003, Ladygin 2008). In addition, the  $\beta$ -ring of Lut may be a substrate for ZEP (Hieber et al. 2000). Thus, the Lut-epoxide cycle is probably driven by the same set of enzymes that the Vio cycle.

The species in which the Lut-epoxide cycle has been studied range into three groups according to their Lut-epoxide cycle pool of pigments (for more details, see Garcia-Plazaola et al. 2007): (i) species such as *Quercus subpyrenaica* (Abadia et al. 1996), *Q. ilex* (Llorens et al. 2002), and *Viscum album* (Matsubara et al. 2003) have very low amounts (1–10 mmol mol<sup>-1</sup> Chl) and Lut-epoxide/VioAntZea ratio < 0.1; (ii) species such as *Q. robur* (Garcia-Plazaola et al. 2002a), the mistletoe *A. miquelii* Thiegh (Matsubara et al. 2003), and *Acacia melanoxylon* (Watson et al. 2004) contain high amounts of Lut-epoxide and the Lut-epoxide/VioAntZea ratio ranges between 0.1 and 1; and (iii) leaves from shade plants such as the tropical tree *Inga sapindoides* (Matsubara et al. 2005), *Laurus nobilis*, and *Umbellaria californica* (Estaban et al. 2007) have a high pool of Lut-epoxide, up to 78 mmol mol<sup>-1</sup> Chl with a Lut-epoxide/VioAntZea > 1. The frequent Lut-epoxide accumulation in shade leaves relies on a slow epoxidation of Lut by ZEP and on the absence of VDE activity in such conditions. The extremely slow conversion of Lut to Lut-epoxide has been suggested to result from a low affinity of ZEP for Lut (Pogson and Rissler 2000) or it could be due to the low availability of this substrate, which is mainly restricted to the intraprotein Lut sites of Lhcb (Morosinotto et al. 2002, Dekker and Boekema 2005). In their review on the occurrence and possible functions of the Lut-epoxide cycle, Garcia-Plazaola et al. (2007) proposed a model describing the relationships between the Lut-epoxide and Vio cycles. In deep shade, both Vio and Lut epoxide may occupy the Vio1 site while the Lut2 site may be occupied by Lut-epoxide instead of Lut, giving rise to very efficient light-harvesting PSII antenna. After exposure to strong light, the displacement of Lut-epoxide by Lut in Vio1, Lut2, and most Lut1 sites gives efficient energy dissipation centers. A greater pool of Lut derived from Lut-epoxide de-epoxidation as compared with Ant and Zea derived from Vio offers the possibility of a rapid and strong engagement of NPQ. Photoprotection may then be stabilized within hours of exposure to strong light by simultaneous engagement of both cycles, the slowly reversible conversion of Lut being proposed to “lock-in” a

primary mechanism of photoprotection (Matsubara et al. 2005). Thus, the Lut-epoxide cycle could serve as an additional, more slowly relaxing mechanism, to accelerate and sustain the development of NPQ (Garcia-Plazaola et al. 2003).

#### 16.4.4 SPECIFIC XANTHOPHYLL CYCLE INVOLVED IN DIATOMS, XANTHOPHYTES, DINOPHYTES, AND HAPTOPHYTES: THE DIADINOXANTHIN CYCLE

The diadinoxanthin (Ddx) cycle involves the Ddx de-epoxidase (DDE), which de-epoxidises the epoxy-xanthophyll Ddx, whereas the Dtx epoxidase (DEP) catalyzes the back reaction (Wilhelm et al. 2006, Garcia-Plazaola et al. 2007) (Figure 16.1). Several publications have reported on the detection and the regulation of DDE and DEP activities in diatoms (Jakob et al. 2001, Goss et al. 2006, Kroth 2007). Homologous sequences to *DDE* and *DEP* genes were found in the genome database of two diatoms, *T. pseudonana* and *P. tricornutum*, and were named VDE-like because they are distantly related to the plant VDE. VDE-like enzyme could be located differently than the VDE protein because the C-terminal region, which could be important for binding the protein to the thylakoid membrane, is uncharged. Coesel et al. (2008) have proposed that VDE-like enzyme could be implicated in the Ddx cycle of these diatoms. In the same way, the *ZEP* gene product is implicated in the reverse reaction. Compared with the enzymes involved in the Vio cycle, much less is known about the Ddx cycle enzymes from algae. The DDE, homologous of VDE, exhibits a different pH-dependance for its activation, which is shifted by at least 0.7 pH unit toward higher pH values (Jakob et al. 2001). The affinity of DDE for the cosubstrate ascorbate is three to four times higher than in the case of VDE (Grouneva et al. 2006). DEP, which catalyzes the back conversion of Dtx to Ddx is almost inhibited under high-light conditions (Mewes and Richter 2002) and can be also inhibited by cadmium (Bertrand et al. 2001, for reviews see Bertrand and Poirier 2005, Poirier et al. 2008; see also the chapter by Solymosi and Bertrand).

Lohr and Wilhelm (1999) have shown that besides the Ddx cycle, some diatoms may also display a Vio cycle, even if the pool size of pigments concerned with the Vio cycle is rather low.

Another xanthophyll cycle has been proposed to operate in green algae, involving L-siphonaxanthin, a xanthophyll present in the siphonaceous genera, in *Ulva olivescens* (Levavasseur 1981) and in a few Prasinophyceae (Latasa et al. 2004). In *Codium fragile* and *Cladophora opaca*, Vershinin and Kamnev (1996) observed a reversible light-induced de-esterification of siphonaxanthin dodecenoate ester (wrongly identified as siphonoin B (Britton et al. 2004)), with siphonaxanthin accumulation in high light and siphonaxanthin dodecenoate ester in low light. More recently, Raniello et al. (2006) described another xanthophyll cycle operating in addition to the Vio cycle in the shallowest populations of the invasive alga *Caulerpa racemosa* var. *cylindracea*. Interconversions between Lut and siphonaxanthin were shown to occur along the day with Lut and siphonaxanthin highest content under high- and low irradiances, respectively. No variations of the siphonaxanthin dodecenoate ester content could be observed by these authors. Thus, besides the conventional Vio and Ddx cycles, which have been exhaustively studied along the last 40 years, several other xanthophyll cycles have been described more recently, which often operate in parallel with the Vio cycle and participate to photoprotection.

#### 16.4.5 XANTHOPHYLL CYCLES AND EVOLUTION OF PLANTS AND ALGAE

As no homolog of VDE protein have been found in prokaryotes, it could be possible that this protein represents an ancient eukaryotic innovation (Coesel et al. 2008). Actually, cyanobacteria cells seem to be totally devoid of any xanthophyll cycle (Lemoine et al. 1993), even if many taxons, such as *Spirulina*, have a high Vio content. However, the lipocalin protein membership of VDE and ZEP suggests that they may have evolved from lipocalin genes of cyanobacterial ancestors that developed an endosymbiotic relationship with a eukaryotic host cell to form the chloroplast of algae and

higher plants (Durnford et al. 1999, Palmer 2003, Charron et al. 2005). The presence of Vio and its precursors Ant and Zea was frequently observed among Rhodophyte species (Schubert et al. 2006) and operation of a total Vio cycle was proved in *G. birdiae* (Ursi et al. 2003). Even if the only Rhodophyte species in which the Vio cycle was reported belong to the Gracilariales (Rmiki et al. 1996, Ursi et al. 2003), the Vio cycle pigments were also detected in other orders such as the Ceramiales and the Corallinales (Schubert et al. 2006). These observations are important on an evolutive point of view because they suggest that the epoxy-Cars involved in the Vio cycle were present early in the evolution of red algae, before their diversification and before the divergence of the Rhodophyta and Chlorophyta from the ancestral chloroplast (Durnford et al. 1999). A truncation of the Vio cycle was observed in the Prasinophycean alga *Mantoniella squamata* Manton and Parke (Goss et al. 1998). In this primitive green alga, the Vio cycle is limited to the Vio-Ant interconversions because of an extremely slow second de-epoxidation step from Ant to Zea due to a reduced affinity of *Mantoniella* VDE for Ant and a much faster epoxidation rate in the algae than in higher plants (Frommolt et al. 2001). This implies that the role of Zea in qE, the pH or energy component of NPQ (Müller et al. 2001) can be replaced by Ant in this alga. Formation of Zea can, however, be obtained by artificially low-pH treatment (Goss et al. 1998).

Lut-epoxide is widespread among photosynthetic organisms and plant tissues. Its absence in algae discards an ancestral origin. Furthermore, it seems that Lut-epoxide concentration is not phylogenetically determined and would depend on ecological constraints as no correlation was found between its presence and recurrent mutations in ZEP (Esteban et al. 2009). Altogether, the xanthophyll cycle operation seems involved in nearly all photosynthetic eukaryotes (terrestrial and marine) in the photoprotection of chloroplast membranes, with the possible exception of the Cryptophyceae class of algae (Stransky and Hager 1970; Rmiki et al. 1999, Ladygin 2008).

#### 16.4.6 THE XANTHOPHYLL CYCLE: THE MECHANISTIC OF THE CYCLE AND ITS IMPLICATIONS IN THE CHLOROPLAST PHYSIOLOGY

The lumen pH is higher than 7.0 and VDE is supposed to be mobile within this compartment (Hager and Holocher 1994). When the light absorption by LHC exceeds both the possibility for its utilization by the transducers and the capacity of energy dissipation mechanisms, lumen acidification takes place. When the pH value is below 6.5, VDE binds to the thylakoid membrane and is activated (Sierfermann and Yamamoto 1975b, Hager and Holocher 1994). The process occurs in a highly cooperative manner, the pH dependence of Vio de-epoxidation exhibiting a cooperativity for protons of about 5.5 and an inflexion point around pH 6 (Pfündel and Dilley 1993, Jahns and Heyde 1999; for a review, see Horton et al. 2008). VDE activity is also regulated by the proton concentration. The highest activity has been observed for pH values lower than 5.8. The acidity also controls the equilibrium between the basic and acidic forms of the cosubstrate ascorbate (Bratt et al. 1995, Eskling et al. 1997). Anyway, the lumen pH cannot fall below 5, otherwise the electron transport at the cytochrome *b<sub>6</sub>f* complex is inhibited (Horton et al. 2008).

Once Ant produced, VDE transfers an electron and a proton from ascorbate to the epoxy group located at the other side of Ant molecule, creating Zea, water, and dehydroascorbate. This implies that the xanthophyll cycle includes a flip-flop movement of the monoepoxidated xanthophyll in the thylakoid membrane. Altogether, the kinetics of the de-epoxidation is likely to be limited by the xanthophyll diffusion within the membrane (Macko et al. 2002). Indeed, the sorting of the Vio molecules from the proteins and their diffusion within the lipid phase to VDE for conversion to Ant exhibit a four to six times higher rate constant than the conversion of Ant to Zea (Yamamoto and Higashi 1978, Härtel et al. 1996), and thus represents the rate-limiting step of de-epoxidation (for a review, see Jahns et al. 2009).

Despite the fact that the expression of the gene encoding VDE has been shown to vary in response to light intensity (Bugos et al. 1999), the control of VDE activity through the modification of the gene expression seems minor (Macko et al. 2002, Deng et al. 2003).

The regulation of the epoxidation reactions is limited and does not involve a control by the stromal pH (Takeguchi and Yamamoto 1968, Siefermann and Yamamoto 1975a). ZEP can be downregulated after exposure of plants to high light (Jahns and Mische 1996, Verhoeven et al. 1996, Reinhold et al. 2008) or under overwintering conditions (Öquist and Huner 2003). The biochemical basis of the regulation is so far unclear but would involve ZEP phosphorylation (Xu et al. 1999; for a review, see Jahns et al. 2009).

A linear relationship has been found between the amount of Zea produced and the capacity for energy dissipation. This dissipation is reflected in the NPQ. NPQ is formed by several components and is therefore kinetically heterogeneous (Horton and Hague 1988). In moderate excess light, that is, in absence of accumulated damaged PSII reaction centers, NPQ is found to form and relax with two major components, reflecting events taking place in the antenna of PSII. These two components are qE (Müller et al. 2001) and the slowly reversible component of NPQ, namely, qI (Jahns and Mische 1996, Verhoeven et al. 1996).

In the mutant *npq1*, which is defective in VDE, most of qE is inhibited (Niyogi et al. 1998), while the double mutant *npq1 lut2* (the mutant *lut2* is unable to synthesize Lut (Pogson et al. 1998)) is devoid in qE, suggesting a role for Lut in qE (Niyogi et al. 2001) or that alteration in the Lut content could indirectly affect qE by disturbing the assembly and structure of the PSII antenna (Niyogi et al. 1997, Pogson et al. 1998, Lokstein et al. 2002). Thus, the Zea molecules produced through the xanthophyll cycle play a crucial role in the NPQ efficiency.

Besides the roles of the xanthophyll cycle in the qE component of NPQ, there are evidences for the involvement of Zea in (i) the photoprotection of the photosynthetic membranes toward stress-induced peroxidations (Havaux and Niyogi 1999, Havaux et al. 2000, Baroli et al. 2003, Havaux et al. 2007, Johnson et al. 2007). Indeed, it was demonstrated that photoinduced peroxidative damage in leaves is highly increased if the Vio cycle operation is inhibited by the addition of dithiothreitol (Sarry et al. 1994); (ii) the control of thylakoid membrane fluidity because a light-induced decrease in membrane fluidity occurs in thylakoid membranes (Gruszecki and Strzalka 1991, Havaux and Gruszecki 1993) when Vio is allowed to convert in Zea under stress, and thus the thermostability of the thylakoid membranes increases (for a review, see Gruszecki and Strzalka 2005). The LHCII prepared from illuminated leaves was shown to be poorer in xanthophyll cycle pigments than the LHCII prepared from dark-adapted leaves (Havaux and Gruszecki 1993). A diffusive displacement of Zea from the Chl–protein (CP) complexes to the surrounding lipid domain (Gruszecki 1995, Havaux and Tardy 1995) has been suggested to increase membrane rigidity; (iii) the regulation of the cyclic electron flow around PSII. In fact, when the Vio content is high, the cyclic flow of electrons around PSII is reduced (Gruszecki et al. 1995); (iv) the removal of active oxygen species formed during a stress through Zea epoxidation (Lichtenthaler and Schindler 1992, Schubert et al. 1994). The Vio formed could be again de-epoxidated. In such a case, the epoxidation could be nonenzymatic (Schubert et al. 1994).

Altogether, the operation of the xanthophyll cycle is strongly dependent on the antenna, the properties of the thylakoids, and on an active Car biosynthetic pathway. These aspects are detailed in the next paragraphs.

#### 16.4.6.1 Role of Antenna Proteins

When the proteins of the photosynthetic apparatus are separated by nondenaturing electrophoresis, Vio is found as a rather high proportion in the free pigment fraction, indicating that Vio is very weakly bound to these proteins (Lee and Thornber 1995). On the other hand, Vio is present at the periphery of the LHC (Kühlbrandt et al. 1994). Thus, the lumen acidification would favor Vio liberation from Vio-binding site in the different peripheral antenna proteins. Thus, the peripheral and weak binding of Vio are therefore two conditions allowing its involvement in the xanthophyll cycle (Demmig-Adams and Adams 1996), whereas Zea would have to return into the LHC to quench the energy (for a review, see Havaux 1998).

The resolution of the crystal structure of LHCII from spinach and pea and the discovery of Vio binding to it (Liu et al. 2004) allowed to get more information on the participation of pigment–protein

complexes in NPQ. Most evidence is given that PSII is dimeric in the appressed grana parts of the thylakoid membranes of green plants. This aggregated state may be stabilized by protein phosphorylation (Kruse et al. 1997), binding with phosphatidylglycerol (Kruse et al. 2000) and with extrinsic proteins (Boekema et al. 2000). PSII antennae associated with dimeric PSII core complexes constitute PSII-LHCII supercomplexes containing two to four copies of trimeric LHCII complexes (LHcb1–3 proteins) per PSII core dimer, together with three “minor” antenna complexes: LHcb4 (CP29), LHcb5 (CP26), and LHcb6 (CP24). Each protein binds at least one Vio molecule in the dark-adapted state (for a review, Dekker and Boekema 2005). Most of the Vio molecules are bound by the trimeric antenna complex LHCII at the peripheral Vio1 site (Liu et al. 2004), while the “minor” monomeric complexes CP29, CP26, and CP24 bind one to two Vio molecules (Ruban et al. 2002), one of which may be at the internal Lut2 site that binds Lut in LHCII (Morosinotto et al. 2002, Wehner et al. 2006). Upon exposure to excess light, VDE leads to the appearance of Ant and Zea. Vio binding from site Vio1 is pH dependent and it is released to provide a source of substrate for VDE. Vio is also liberated from the minor complexes providing empty Car-binding sites for newly formed Zea (Morosinotto et al. 2003). The liberated Vio molecules are dissolved in the thylakoid membrane lipids. Their de-epoxidation by the lumenal enzyme VDE needs the binding of VDE to the thylakoid membranes to provide access to its substrate. Monomeric antennae, especially CP26 and CP24, show high binding rates and these proteins are probably one of the sites where Zea plays its function (Morosinotto et al. 2003). Some Zea binding to the peripheral LHCI antenna of PSI was also observed (Morosinotto et al. 2002), suggesting a PSI response to the environmental stress conditions.

#### 16.4.6.2 Change of Light Harvesting Complex Properties

The detailed relationship between qE and the operation of the xanthophyll cycle is still unknown. Actually, the biophysical mechanism of energy quenching in qE remains controversial because two mechanisms, although nonexclusive, have been proposed. The first model implies a direct role of Zea in the antenna via the formation of a quenching complex with a short fluorescence lifetime (Gilmore et al. 1995). Zea operates in the quenching through a charge-transfer mechanism (Holt et al. 2005) in the minor LHC complexes associated with PSII, that is, CP29 (Lhcb4), CP26 (Lhcb5), and CP24 (Lhcb6) (Ahn et al. 2008, Avenson et al. 2008, 2009). The charge-transfer mechanism involves an energy transfer from closely coupled Chl and Zea molecules that transiently produce pigment ions, a Chl anion and a Zea cation, respectively (Frank et al. 1994). The subsequent charge recombination dissipates the excitation energy as heat.

In the second model, Zea is not required for qE (Rees et al. 1989, Horton et al. 1996, Havir et al. 1997) but is involved as an indirect allosteric regulator (Crouchman et al. 2006, for a review, see Horton et al. 2008) of the pH sensitivity of qE (Noctor et al. 1991). In this model, qE arises from a conformational change (Horton et al. 1991) in the peripheral, trimeric antenna of PSII (Pascal et al. 2005) and its mechanism involves an energy transfer from Chl to Lut1 (Ruban et al. 2007). Evidences that these events are of a cooperative nature, that is, involving interactions between subunits of PSII antenna have been presented (Noctor et al. 1991, Ruban et al. 2001). The interactions between LHCII proteins are influenced by divalent cations. The influence of the changes in their concentration of the curve qE *versus* lumen pH supports the cooperative nature of qE (Noctor et al. 1993). According to the model, the LHCII can exist under four states (Horton et al. 1991; for a review, see Horton et al. 2008). During the transition State I to State III, the lumen acidifies rapidly and LHC proteins are protonated. The intensity of the lumen acidification is, however, insufficient to saturate qE. The transition State III and State IV occurs while VDE takes place and the qE slowly builds up. When the light source is turned off, qE relaxes following the collapse of the  $\Delta$ pH. If the light source is again switched on, qE increases very rapidly to its maximum capacity because the Zea molecules formed during the previous illumination keep the photosynthetic apparatus “light activated”. In this case, the system shifts rapidly from State II to State IV, allowing photosynthesis and energy dissipation through qE to function at its maximal rates (Horton et al. 1991; for reviews,

see Horton et al. 1996, Horton et al. 2008). Using the double mutant *npq1 lut2*, Li et al. (2009) obtained evidences for the first mechanism and also for the involvement of Lut in qE.

Among the additional factors involved in both mechanisms, PsbS, a small Lhc-like protein, was shown to have a key role in the dissipation of excess energy in higher plants (Li et al. 2000) and there is evidence that its level is correlated with the extent of NPQ (Li et al. 2002). Upon lowering of the luminal pH, a rapid response, prior to xanthophyll cycle operation, called quenching 1 by Morosinotto et al. (2003) was shown to involve protonation of luminal exposed acidic residues of PsbS. More recently, PsbS has been proposed to form a quenching complex together with LHCII and Zea (Bonente et al. 2008). Thus, PsbS would act as a sensor of lumen acidification that triggers conformational changes in the PSII antenna such as LHC aggregation (Garab et al. 1988, Croft and Yerkes 1994, Horton et al. 1994, Ruban and Horton 1994, Walters et al. 1994, Ruban et al. 1997), triggering a more efficient Chl deexcitation (Ahn et al. 2008, Avenson et al. 2008, Horton et al. 2008). The aggregation may be stimulated by the addition of Zea and inhibited by Vio (Ruban et al. 1997). The action of the pigments would be mediated by their difference in hydrophobicity, that is, Zea is much more hydrophobic than Vio (Ruban et al. 1993, Darko et al. 2000). This would fit with the fact that the transmembrane organization of the xanthophyll cycle, with VDE in the thylakoid lumen and ZEP located on the stromal side, implies a certain freedom of movement of the xanthophyll cycle pigments in the membrane lipid to allow contact between the enzymes and the head group of the xanthophylls. A role for Elips and Ohps, two groups of PsbS-related stress-induced proteins, was suggested in the xanthophyll cycle-associated photoprotection (Demmig-Adams et al. 2006, Zarter et al. 2006).

#### 16.4.6.3 Role for Membrane Lipids

Activity *in vitro* of VDE was shown to require MGDG, the main lipid of thylakoid membranes (Yamamoto and Higashi 1978), and the essential role of this lipid for VDE activity in liposomes was further confirmed more recently (Goss et al. 2006). Because Vio molecules are liberated in the lipid phase of membranes, VDE needs to bind to the membrane for its activity. It was proposed that VDE would attach to MGDG-enriched membrane domains where de-epoxidation would occur (Latowski et al. 2002). In liposomes composed of phosphatidylcholine and MGDG, as in native thylakoid membranes, inverted hexagonal structures ( $H_{II}$ ) have been described (Quinn and Williams, 1983). In such liposomes, VDE activity depends on the rate of lateral diffusion to MGDG domains and thus on the MGDG/Vio ratio (Latowski et al. 2002). The presence of ( $H_{II}$ ) phases in the MGDG domains facilitates the flip-flop movement of the Ant molecule to allow VDE access to the second epoxy group and conversion of Ant to Zea. An updated model for the mechanism of xanthophyll conversions was recently proposed by Jahns et al. (2009). In this model, the presence of  $H_{II}$  domains and Vio molecules free in MGDG phases are required. They also propose that the transition to the light-adapted state is accompanied by aggregation of LHCII complexes, which facilitates the liberation of Vio molecules from the external VioI-binding sites. After binding of VDE to the MGDG phases, Vio is de-epoxidized into Zea. The decreased solubility of Zea in MGDG compared with phosphatidylcholine facilitates reentrance of Zea in the bilayer phase of the membranes where the antenna proteins are located. The binding of Zea to the minor antenna proteins of PSII (Lhcb4–6) could facilitate the dissipation of energy *via* a Zea cation radical.

#### 16.4.6.4 Xanthophyll Cycle Pool of Pigments Is Dynamic

So far, we described the xanthophyll cycle as a device catalyzing pigment interconversions. There are more and more results suggesting that, in fact, the amount of pigments in the xanthophyll cycle pool depends on the environmental conditions but is also adjusted quantitatively as a function of the stress intensity (Esteban et al. 2007). For instance, in the two Pheophyceae, *Pelvetia caniculata* and *Laminaria saccharina*, the amounts of Zea accumulated through the operation of the xanthophyll cycle operation after a light stress are very different on a Chl *a* basis. Such a difference has been shown to be one of the main factors responsible for the specific distributions of these two species at opposite levels on the seashore (Harker et al. 1999). Duckweed (*Lemna minor*) plants grown under

high light present a higher xanthophyll cycle pool of pigments and also a higher proportion of transformable Vio than the plants grown under low light. When plants were transferred to a high-light environment, a quick adjustment of the Car composition was observed. It mostly concerns the pigments involved in the xanthophyll cycle. This increase in pigments results of a *de novo* synthesis of Cars because in the presence of norflurazon, an inhibitor of carotenogenesis, this increase is inhibited. The extent of this light-induced synthesis is proportional to the light treatment and also on the operation of the xanthophyll cycle. Accordingly, the inhibition of the xanthophyll cycle by dithiothreitol also abolished the light-induced carotenogenesis (Garcia-Plazaola et al. 2002b).

## 16.5 SECONDARY CAROTENOID AND APOCAROTENOID BIOSYNTHESIS IN ALGAE AND HIGHER PLANTS

Cars are found in all photosynthetic organisms and in some bacteria and fungi (for a review, see Almeida and Cerda-Olmedo 2008, Lemoine et al. 2008). While primary Cars constitute functional components of the photosynthetic apparatus, the secondary Cars are accumulated in oil droplets in the cytoplasm or in the plastids.

Car synthesis has been investigated since the mid-1960s and the genes for almost all the enzymes involved in this biosynthesis have been cloned and analyzed in various organisms (Ye et al. 2008). Two distinct pathways may produce the isoprenoid precursor, isopentenyl diphosphate (IPP): the cytosolic mevalonate pathway and plastidic nonmevalonate or methylerythritol 4-phosphate (MEP) pathway (Das et al. 2007). The MEP pathway seems to be the favored way to synthesize Cars in higher plants (DellaPenna and Pogson 2006) and the acetate/mevalonate pathway was shown to be absent in chlorophytes (Schwender et al. 2001). The condensation of glyceraldehyde-3-phosphate and pyruvate gives the 5-carbon compound IPP and its isomer dimethylallyl pyrophosphate. A series of condensation reactions of one dimethylallyl pyrophosphate molecule and three IPP molecules gives the 20-carbon geranyl diphosphate, which produce the 40-carbon Car precursor phytoene. Successive desaturation reactions catalyzed by phytoene desaturase and  $\zeta$ -carotene desaturase yield lycopene. Lycopene is cyclized into  $\beta$ -carotene, a nonoxygenated Car, by the lycopene  $\beta$ -cyclase (LCY-B). The oxygenated derivatives of carotenes are designated as xanthophylls—the key components of the LHCs (DellaPenna and Pogson 2006). The Car metabolism is not limited to the chloroplast in photosynthetic organisms since  $\beta$ -carotene oxidation into astaxanthin occurs in the cytosol of *Haematococcus pluvialis*, and it has been shown in *Marchantia polymorpha* that the complete synthesis of Cars occurs in cytoplasmic oil bodies (Suire et al. 2000). Xanthophylls can also be metabolized further into Apocars.

### 16.5.1 SECONDARY CAROTENOIDS IN MICROALGAE

Despite the fact that several green microalgal species such as *H. pluvialis*, *Dunaliella* sp., *Neochloris wimmeri*, *Scenedesmus vacuolatus*, *Scotiellopsis oocystiformis*, *Chlorella zofingiensis*, and *Protosiphon botryoides* are able to accumulate secondary Cars under stressful environmental conditions (Kopecky et al. 2000, Orosa et al. 2000), most of the studies have been performed on *Dunaliella* sp. and *H. pluvialis*, probably because these two taxons are used for the commercial production of Cars (e.g., Zhang et al. 1999, Das et al. 2007).

#### 16.5.1.1 *Dunaliella* sp.: A Model for the Study of $\beta$ -Carotene Biosynthesis

*Dunaliella salina*, a halotolerant alga, accumulates large amounts of  $\beta$ -carotene (up to 10% of the dry algal biomass) under high light intensity, high salinity, high temperature, heavy metal stress, and/or insufficient nitrogen and phosphate conditions (Ramos et al. 2008). The other Cars synthesized are  $\alpha$ -carotene, Lut, Zea, cryptoxanthin, and neoxanthin. The cell color of *Dunaliella* changed from green to orange-red following Car accumulation (Lamers et al. 2008). Because *D. salina* accumulates high amounts of  $\beta$ -carotene under stress conditions, the culture of this alga

is the most important process for natural production of this Car. This alga thus represents a useful model to understand the mechanism of Car formation (Ye et al. 2008). Enzymes and intermediates in the nonmevalonate pathway are seldomly analyzed, but more information would be obtained after the release of the genome sequence now under sequencing on the DOE Joint Genome Institute Web site (<http://www.jgi.doe.gov/>). In biflagellate and motile cells and especially under carotenogenic conditions, the  $\beta$ -carotene was accumulated as lipid globules in the interthylakoid spaces of the cell's single chloroplast. This membrane-free lipid globule exclusively contained more than half of  $\beta$ -carotene, neutral lipids, and a small amount of a protein (38 kDa) called the carotene globule protein that could stabilize the lipid globule within the chloroplast (Hadi et al. 2008, Ye et al. 2008).

Car synthesis in *Dunaliella* has recently been shown to proceed *via* the MEP pathway (Caparobles et al. 2009). Key sequences of the carotenogenesis production were isolated from a few species of *Dunaliella* taxon and sequenced: 1-deoxyxylulose-5-phosphate synthase (DXS), responsible of the first step in the biosynthesis of IPP, phytoene synthase, phytoene desaturase, and LYC, which catalyzes cyclization at both ends of the linear lycopene to form cyclic  $\beta$ -carotene (Yan et al. 2005, Sanchez-Estudillo et al. 2006, Zhu et al. 2008).

During environmental stress, the generation of ROS, which damage proteins, carbohydrates, and DNA, triggers the accumulation of internal antioxidants such as  $\beta$ -carotene in *Dunaliella* (Murthy et al. 2005, Ye et al. 2008). The 9-*cis* stereoisomer is more efficient than all-*trans*- $\beta$ -carotene in scavenging of ROS (Ye et al. 2008). These properties of the Cars explained in part why the medical science used these molecules against many kinds of human diseases (Handelman 2001, Higuera-Ciapara et al. 2006).

Triacylglycerol biosynthesis and the carotenogenesis were shown to be interdependent in *Dunaliella* (Rabbani et al. 1998), newly formed lipid droplets being necessary for the accumulation of  $\beta$ -carotene. Lipid metabolism is also affected by the increase of the volume of *Dunaliella* cells because they are surrounded by a thin elastic membrane, and the membrane composition changes under stress conditions (Murthy et al. 2005, Ye et al. 2008).

#### 16.5.1.2 *Haematococcus pluvialis*: A Model to Study Astaxanthin Biosynthesis

The main factors inducing astaxanthin accumulation in *H. pluvialis* are low nitrate, high light, and high temperature (Lemoine et al. 2008). Several genes, such those coding IPP isomerase, phytoene synthase (PSY), phytoene desaturase (PDS), lycopene  $\beta$ -cyclase (LCY-B), and  $\beta$ -carotene ketolase, involved in the Car biosynthesis are activated under stress conditions.

Astaxanthin biosynthesis is the most studied secondary Car and is produced by  $\alpha$ -proteobacteria, fungi, and plants (Tao et al. 2006, Martin et al. 2008). Astaxanthin is synthesized from  $\beta$ -carotene but the biosynthesis pathways in bacteria, fungi, algae, and plants differ (Martin et al. 2008). In *H. pluvialis*, the first astaxanthin molecules are synthesized at the expense of the  $\beta$ -carotene molecules taken from the photosynthetic apparatus. To sustain the large accumulation of astaxanthin molecules, a *de novo*  $\beta$ -carotene synthesis is triggered when the  $\beta$ -carotene pool, present before the stress, is almost exhausted (Schoefs et al. 2001). Regardless of their origin, the  $\beta$ -carotene molecules are exported in the cytoplasm in lipid vesicles where they are transformed into astaxanthin that are, in turn, esterified with fatty acid molecules (for a review, see Lemoine et al. 2008). The astaxanthin biosynthesis route is now quite well defined:  $\beta$ -carotene is transformed into echinenone after ketolation with either canthaxanthine or hydroxy-echinenone as a first intermediate and further hydroxylation of adonirubin (Schoefs et al. 2001). The use of a pharmacological approach has shown that the other routes *via* adonixanthin are poorly performed (Fraser et al. 1998; Hirschberg 1998, Schoefs et al. 2001). There is at least a  $\beta$ -carotene hydrolase belonging to the cytochrome P-450 monooxygenase protein superfamily that is involved in this pathway (Schoefs et al. 2001). In the fungus *Xanthophyllomyces dendrorhous*, the conversion of  $\beta$ -carotene into astaxanthin could be catalyzed by a single multifunction  $\beta$ -carotene oxidase (Ojima et al. 2006) by the combined activity of a  $\beta$ -carotene hydroxylase and a  $\beta$ -carotene ketolase working successively on different intermediates (Martin et al. 2008).

Some Car could be produced through chemosynthetic pathway but they are devoid of stereoisomers. To produce Cars, researchers used engineered microorganisms such as *E. coli* and yeast or transgenic plants such as *Oryza sativa* employing transformation with carotenogenic genes (Ye et al. 2008). The carotenogenesis genes of *D. salina* and *H. pluvialis* may promote massive accumulation of Cars in heterologous expression systems. The genome of *D. salina* could be used as a tool to identify and find the sequences of enzymes such as the isomerase involved in the formation of Cars with the active configuration.

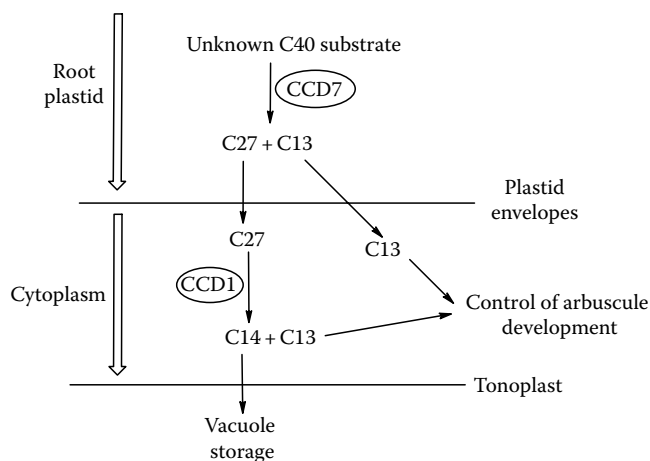

### 16.5.2 ROOT COLONIZATION BY ARBUSCULAR MYCORRHIZAL FUNGI TRIGGERS THE PRODUCTION OF SECONDARY CAROTENOIDS AND APOCAROTENOIDS

Most of land plants form mutualistic association or symbiosis with soil-borne fungi. The arbuscular mycorrhizal symbiosis is the most frequently encountered since it concerns *ca.* 80% of the plants and 90% of crop plants. In arbuscular mycorrhizal symbiosis, the fungus colonizes root cortical cells forming highly branched structures, the so-called arbuscule, that facilitates the uptake of the soil nutrients such as phosphate, nitrate, or water, while the plant partner provides the fungus with photosynthetically synthesized carbohydrates (up 20% of plant-fixed carbon) (Parniske 2008). The formation of the arbuscules leads to a complex and profound reorganization of the subcellular structures of the cortical cells including a massive proliferation of the plastids of the colonized root cortical cells. These plastids are connected to each other by stromules (Köhler et al. 1997, Tobin 1997; for a review, see Fester 2008), forming a dynamic network that is formed and degraded with the formation and the senescence of the arbuscules (Fester et al. 2001, Strack and Fester 2006; for reviews, see Bonfante-Fasolo 1984, Gianinazzi-Pearson 1996). In root plastids, different sets of enzymes catalyze numerous biochemical processes such as those leading to the production of fatty acids, amino acids, purines and pyrimidines, nitrogen assimilation, and isoprenoids (Miernyk 1985, Daher et al. 2010). The activities of these pathways are enhanced during mycorrhization suggesting a crucial role for the plastids in the accumulation of Apocars and during the mycorrhization (Fester et al. 2001, 2007, Lohse et al. 2005). In particular, the cellular program driving the colonization contains lines specifying reorientation of the root plastid metabolism to the production of secondary metabolites including Cars and Apocars to a point that the white roots become yellow when colonized (Klingner et al. 1995, Fester et al. 2002a, Schliemann et al. 2006). The core structure of the yellow pigment contains an acyclic C14 polyene, namely, mycorradicin. This pigment is accompanied by a C13 cyclohexenone diglucoside (Fester et al. 2002a, Walter et al. 2007). Both Apocar types are actually present as mixture because they are differently esterified (Maier et al. 1995, Fester et al. 2002a) and their production results of the oxidative cleavage of a common Car precursor (Walter et al. 2000). The Apocars are massively deposited in the vacuole (Klingner et al. 1995) and probably in the cytoplasm too (Fester et al. 2002a). The accumulation of the yellow pigments mostly occur during the late phase of mycorrhization, that is, during arbuscule degradation, phase of the mycorrhization process during which the plastid network is disintegrated (Fester et al. 2001).

#### 16.5.2.1 Biosynthesis of Apocarotenoids

The activation of the AM-dependent MEP pathway has been demonstrated for *Medicago truncatula* (Lohse et al. 2005, Floss et al. 2008a). Northern blot experiments showed an increase of the transcript levels of the DXS2 and 1-deoxy-xylulose-5-phosphate reductoisomerase, the first enzymes of the plastids-located MEP pathway, in AM roots from wheat, maize, rice, and barley (Fester et al. 2007, Walter et al. 2000, Walter et al. 2000, 2002, 2007). Transcript levels of the genes coding the enzymes involved in the Car pathway such as PDS and  $\zeta$ -carotene desaturase increase in the AM roots of *Nicotiana tabacum* (Strack and Fester 2006) but no Car accumulates because they are further metabolized into Apocars through the action of Car cleavage dioxygenase (CCD) enzymes, the production of which is induced by colonization by AM fungi (Strack and Fester 2006).

**FIGURE 16.2** Scheme presenting the biochemical pathways of mycorradicine (C14) and cyclohexenone (C13) in response of mycorrhization.

CCD activities exhibit a high degree of regiospecificity and stereospecificity. They give rise to a variety of products with different biological functions as Apocar aromatic volatiles of flower scents, fruit aroma, phytohormones such as abscissic acid, and strigolactone (Akiyama 2007, Garcia-Garrido et al. 2009). Using a very elegant approach, Floss et al. (2008a) demonstrated that the CCD enzyme that uses the C40 Car precursor is CCD7. It has been shown that CCD7 cleaves Cars asymmetrically, producing C13 and C27 fragments (Bouvier et al. 2003, Rubio et al. 2008) (Figure 16.2). Another candidate for the catalysis of the reaction would be CCD4, but expression data have shown that this enzyme is not produced in roots (Ohmiya et al. 2006, Floss et al. 2008a, Rubio et al. 2008). This reaction takes place in the plastids, and the products are exported to the cytoplasm where they are further metabolized by the CCD1 enzyme into C13 cyclohexenone and C14 mycorradicin (Floss et al. 2008a, Vogel et al. 2008) (Figure 16.2). This scheme fits with the subcellular localization of the enzymatic activities. CCD1 that is able to directly split up a C40 into C13 and C14 (Schwartz et al. 2001) is the only CCD to be localized outside plastids (Bouvier et al. 2003, Tan et al. 2003, Aldridge et al. 2006) and, consequently, it has no access to the C40 precursor. Thus, it is its second catalytic activity (cleavage at the 5,6/5',6' positions) that is at work in the cytoplasm (Figure 16.2). These results highlight that, to really understand the functioning of a biochemical process such as the production of Apocars, it is crucial to consider the subcellular localization(s) of the enzymatic activities (for reviews, see Schoefs 2008, Seddas et al. 2009).

The Car fragments are partly esterified and deposited as small lipophilic droplets in the vacuoles of root cortical cells (Strack and Fester 2006). Traces of  $\zeta$ -carotene were detected and no accumulation of other detectable intermediates suggested that the biosynthesis of the accumulating Apocars appeared to proceed rapidly (Fester et al. 2007). Very importantly, the accumulation of these secondary Apocars is restricted to the colonized cells because the expression of the *DXS2* gene increases only in these cells (Floss et al. 2008b), reinforcing the idea that plastids play a crucial role in the metabolism of these cells.

Another type of secondary Apocars, such as the strigolactone family of molecules, is produced by plant roots (Akiyama 2007, Garcia-Garrido et al. 2009). Their synthesis would also involve CCD7 but in this case, the C27 product would be cleaved into a C9 and a C18 products through the catalytic action of CCD8 (Schwartz et al. 2004; Alder et al. 2008) (Figure 16.2).

### 16.5.2.2 Roles and Functions of Secondary Apocarotenoids

Strigolactones, a novel class of plant hormone, are released usually in trace amounts from the roots on phosphate deficiency but in sufficient amount to be detected by new potential hosts (Strack and Fester 2006, Garcia-Garrido et al. 2009, Seddas et al. 2009). Strigolactone stimulates spore

germination in some AM fungi (Parniske 2008) and induces a continued hyphal growth and a profuse branching of hyphae, and could also activate the respiration of the arbuscular mycorrhizal fungi (for a review, see Seddas et al. 2009).

Abscissic acid, another plant hormone, is an Apocar. A possible role of the abscissic acid in AM roots was suggested because the level of this phytohormone increases during the fungal symbiosis in *Zea mays* and *Glycine max* (Strack and Fester 2006, Parniske 2008, Seddas et al. 2009).

The accumulated Apocars C13 and C14 may have structural functions and could provide efficient protection against oxidative stress (ROS scavenging) as the general antioxidant function of Cars accumulated under environmental stress (Fester et al. 2002b, Floss et al. 2008a). ROS could act as second messengers inducing the Car biosynthesis and/or are required for signaling fungal cell death (Strack and Fester 2006). Mycorradicin might play a role in the detoxification of  $H_2O_2$  generated during the arbuscule disintegration. Apocars may protect membranes from oxidative damage, limiting oxygen penetration to the hydrophobic membrane core (Strack and Fester 2006).

In plants having *CCD1* gene silenced, the amount of C13 cyclohexenone decreased strongly, whereas the amount of senescent or dead arbuscules increased (Floss et al. 2008b). Therefore, it was proposed that cyclohexenone is involved in the control of the duration of the functionality of arbuscules (Walter et al. 2007, Floss et al. 2008b). This conclusion fits with the fact that exogenous blumenin shows a negative influence on AM (Fester et al. 1999, Walter et al. 2007). In contrast, cyclohexenone derivatives (other C13) were not responsible for the systemic suppression of mycorrhization in pre-colonized barley plants (Vierheilig et al. 2000), and mycorradicin did not suppress an elicitor-induced oxidative burst reaction in *N. tabacum* and *Medicago sativa* cell cultures (Schröder et al. 2001).

## CONCLUSIONS AND PERSPECTIVES

Cars and Apocars are commonly concerned in biotic and abiotic stresses. They participate efficiently to the various plant responses and in these sense, they constitute a crucial element of the plant survival strategies. An essential function of Cars is to prevent the chloroplasts against harmful photooxidative reactions either through a direct dissipation of the excess of energy as heat or by participating in the formation of the NPQ through their involvement in the xanthophyll cycle. Besides these contributions to plant physiology, Cars and Apocars act as storage compounds, allowing stressed algae to overcome the disruption of the photosynthetic activity triggered by the stress. Many progresses that have been performed in the elucidation of the metabolic pathways leading to the production of the Cars, and physiological studies have suggested that previously described catabolic pathways, might actually be metabolic and/or regulation pathways. Thus, they do not solely correspond to degradation of useless molecules but they could produce crucial actors of plants physiology such as strigolactones and cyclohexenones. This has opened completely new avenues for research in different fields of plant sciences. Altogether, the central role of different types of plastids (chloroplasts and root plastids) in plant life is strongly reinforced.

## 17.1 INTRODUCTION

Desiccation-tolerant (poikilohydric) plants represent a unique group of organisms, which are able to withstand loss of water to an air-dry state and to survive extended periods of severe water deficit [1,2]. Poikilohydry is a relatively common phenomenon in nonvascular taxa such as lichens, algae, and bryophytes, but only 74 pteridophytes and 145 angiosperms belong to these so-called resurrection plants [3]. In a desiccated state, their physiological functions, including photosynthetic activity completely ceased, but during rehydration this activity can be fully restored, with different rates in homoiochlorophyllous (HDT) and in poikilochlorophyllous (PDT) desiccation-tolerant plants [4,5].

Various aspects of the desiccation tolerance in vascular plants have received considerable attention, the latest efforts being focused on clarifying the physiological and molecular basis of this phenomenon [6–20]. However, until now the exact mechanisms which preserve the highly sensitive photosynthetic system in HDT plants during desiccation, and the characteristics of the recoverable photosynthetic system in the desiccated stage are still not well understood. The complete reconstitution of chloroplast structure and functional activity in resurrection plants on rehydration suggests some peculiarities of thylakoid membrane and/or chloroplast stroma composition [21,22], which make these plants a very suitable model system for investigation of photosystem II (PSII) complex perturbations and its adaptive plasticity in the course of desiccation and rehydration.

During our studies of *Haberlea rhodopensis* Friv., using a highly sensitive thermoluminescence (TL) technique, we observed some peculiarities of PSII redox reactions that can reflect some specific adaptive characteristics of the photosynthetic system, related to desiccation tolerance of this resurrection plant. In addition to multiple mechanisms for chloroplast integrity preservation, the observed stabilization of charge storage in PSII complex together with a strong reduction of the total number of PSII centers without any changes in their energy status, can explain the fast recovery of the photosynthetic activity after desiccation.

## 17.2 STRATEGIES OF RESURRECTION ANGIOSPERM *HABERLEA RHODOPENSIS* TO PRESERVE CELL INTEGRITY

The Balkan endemic *Haberlea rhodopensis* Friv. (Gesneriaceae) is a unique species of European flora, (spread in Bulgaria and Northeastern Greece), belonging to a very small group of desiccation-tolerant vascular flowering plants (Figure 17.1C). The current distribution of the plants is restricted to the northern rocky slopes of gorges and canyons, mainly of foothills, sometimes reaching the alpine belts. Its natural habitats are characterized by high mean annual temperatures (of about 20°C), frequent mist and dew fall in the early morning hours and in the evening, and high periodic rainfalls totaling about 600 mm annually. Besides episodic droughts and high temperatures, pronounced short and long-term changes in irradiance may be the major environmental constraints affecting water balance and photosynthetic activity of these rosette plants.

Homoiochlorophyllous desiccation-tolerant (HDT) plants evolve various morphological and physiological mechanisms to preserve their intrachloroplastic membrane system and photosynthetic apparatus in an easily and rapidly recoverable form, which can be ready to function in a normal way immediately after rehydration, following the desiccated stage [5]. During drying, a controlled folding of *Haberlea rhodopensis* leaves occurs (Figure 17.1A) with the abaxial surface exposure to light thought to be an important protective strategy in HDT plants to preserve their chloroplasts from photoinhibitory damages [23–25]. Simultaneously, a phenomenon of leaf surface decrease (more than 60% compared to fully hydrated leaves), accompanied by a reduction in specific leaf area, was also observed for *H. rhodopensis* leaves, dehydrated to about 30% relative water content (RWC) [26].

These typical resurrection plant reactions, which minimize mechanical damage, are due to cell volume reduction in conformity with cell walls folding (Figure 17.2B). The lack of significant differences in the electrolyte leakage between fully hydrated, desiccated, and rehydrated *H. rhodopensis* leaves confirms the preservation of membrane integrity (Table 17.1). In contrast to desiccation-tolerant species, the observed leaf surface decrease in mesophytic spinach during desiccation was only 20%, which disturbed membrane integrity and induced irreversible injuries of the cell membranes, leading to further substantial increase in leakage upon rehydration of the leaves (Table 17.1). We also found clear differences in the level of MDA, H<sub>2</sub>O<sub>2</sub>, and proline accumulation between *H. rhodopensis* and spinach leaves, confirming the symptoms of injury in non-tolerant plants.

**FIGURE 17.1** Morphological changes in the resurrection plant *Haberlea rhodopensis* Friv. (Gesneriaceae). (A) Desiccated plant. (B) Fully hydrated plant. (C) *Haberlea rhodopensis* plants in their natural habitat.

**FIGURE 17.2** Light microscope micrograph cross-sections from detached leaves of the homoiochlorophyllous resurrection plant *Haberlea rhodopensis* treated in the dark. (A) The fully hydrated leaf shows extended oval cells with a large central vacuole and peripheral location of the chloroplasts. (B) Dehydrated to 20% RWC leaf. The cells become smaller with irregular shape, the central vacuole have shrunk or even disappeared, with a formation of several small vacuoles, the chloroplasts are scattered in the cytoplasm. (C) During rehydration for 12 h, the cells have notably restored their normal shape and plastid location. Bars = 20  $\mu\text{m}$  (left) and 100  $\mu\text{m}$  (right).

The protection against desiccation damage in angiosperms is linked to the accumulation of carbohydrates, various compatible solutes and specific proteins as well as some changes in lipid composition. The analysis of mainly carbohydrates in the leaves of *H. rhodopensis* showed dextrans, sucrose, fructose, glucose, and starch [27]. During drying, starch content declined and large quantities of sucrose [27,28] was accumulated.

Similarly, the lipid and sterol compositions of leaves of *H. rhodopensis* changed significantly during drying [29]. The most substantial changes were observed at 50% water deficit, where linolenic

acid concentration diminished, but the campesterol/sitosterol ratio increased, causing membrane stabilization. The authors suggested that the highest proportion of DGDG (a bilayer-forming lipid) may play a role in the control of ionic permeability in the *H. rhodopensis* chloroplasts. An increased DGDG/MGDG ratio upon dehydration was also found after water stress in a tolerant variety of *Vigna unguiculata* [30], in a drought-tolerant cultivar of wheat [31], in *Ramonda serbica* [29,32], and in *Sporobolus stapfianus* [33]. Different arrangements of MGDGs and DGDGs within the thylakoid membranes [34] and changes in their proportions correlate with its physical properties.

### 17.3 FUNCTIONAL FEATURES OF PHOTOSYSTEM II IN *HABERLEA RHODOPENSIS* LEAVES STUDIED BY THERMOLUMINESCENCE

#### 17.3.1 PECULIARITIES OF THERMOLUMINESCENCE EMISSION FROM *HABERLEA RHODOPENSIS* LEAVES

*H. rhodopensis* belongs to the group of homoiochlorophyllous poikilohydric dicotyledons, which upon desiccation preserve above 80% of the chlorophyll, and its photosynthetic apparatus is able to recover very fast [35,36]. Moreover, *H. rhodopensis* has the rare ability of its resurrection occurring in detached leaves (and even a small leaf disk). Young, fully expanded leaves, from the middle of rosettes, of similar size and appearance were used in the measurements. In order to distinguish the direct effect of water loss on photosynthetic activity and to avoid photoinhibition, the dehydration of detached leaves was carried out under dark conditions. For the purpose of comparison, experiments with leaves of the desiccation-sensitive mesophytic plant *Spinacia oleraceae* L. (Chenopodiaceae) were also done.

TL glow curve parameters were used to access the functional features of PSII. TL proved to be a very sensitive and reliable biophysical method for investigation of the functioning of both PSII donor and acceptor side components (see Refs. [37–39] for review). TL signals have been assigned to result from the thermal-activated recombination of the trapped electrons and stabilized positive equivalents on the reduced quinone acceptors ( $Q_A$  or  $Q_B$ ) and on the  $S_2$  (or  $S_3$ ) oxidation state of the water-splitting complex, respectively. Figure 17.3 shows TL curves of *H. rhodopensis* leaves in comparison to those from spinach. Excitation of dark-adapted spinach leaves with a single flash (F), generating a  $S_2Q_B^-$  charge pair, induced a B band peaking at around 32°C (Figure 17.3A), which was

**FIGURE 17.3** TL from fully hydrated dark-adapted *Haberlea rhodopensis* (solid line) and spinach (dashed line) leaves excited with one (A) and two (B) saturating flashes at 5°C. (C) Leaves infiltrated with 20  $\mu$ M DCMU and excited at  $-10^{\circ}\text{C}$  with one saturating flash. Leaf disks with a diameter of 10mm were used in the experiments.

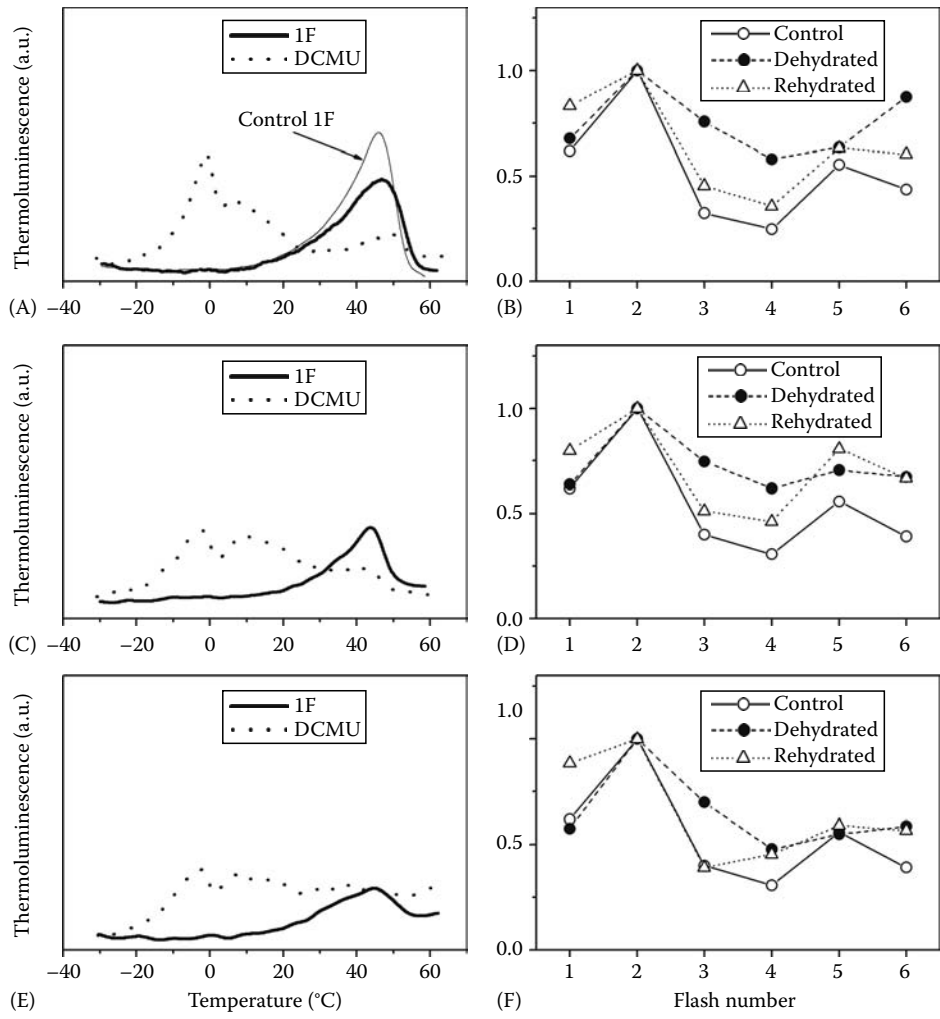

usually observed in the higher plants [40]. The most striking feature of the TL emission observed in the *H. rhodopensis* leaves was the upshift of the B-peak emission temperature to about 45°C. Similarly, different emission temperatures were registered when two ( $S_{2(3)}Q_B^-$ ) flashes were given (Figure 17.3B). The B band position at higher temperature is indicative of more stably stored  $S_{2(3)}Q_B^-$  charge pairs in the resurrection plant [41]. With intact, photosynthetically active cells, such a high TL B band emission temperature had been reported for other types of stress-tolerant organisms, namely thermophilic cyanobacterium or desiccation-tolerant ferns and lichen [22,42,43].

The high emission temperature of the TL B band from *H. rhodopensis* leaves could be attributed to some changes in the properties of redox partners on the donor or on acceptor side of PSII, or both. One way to test the contribution of  $Q_B^-$  is to monitor TL after infiltration of the leaves with 3-(3,4-dichlorophenyl)-1,1-dimethylurea (DCMU), which specifically inhibits the electron transport between the primary ( $Q_A$ ) and the secondary ( $Q_B$ ) quinone acceptors. Recordings on Figure 17.3C show that DCMU treatment of spinach leaves leads to a significant downshift in B band position, concomitantly with a decrease in its amplitude and the appearance of a new, so-called Q band, peaking at around 0°C, which is thought to originate from  $S_2Q_A^-$  charge recombination [40]. In 20  $\mu$ M DCMU treated *H. rhodopensis* leaves disks the Q band also appeared at approximately the same temperature. Since the S states are the common pole for positive charges of the B and Q band, the distinct differences of B-peak temperature position in *H. rhodopensis* and spinach leaves suggest major alterations in the redox property of  $Q_B^-$  in the resurrection plant. Surprisingly, a part of B band was still clearly expressed even at higher inhibitor concentrations. These results show that some PSII reaction centers in *H. rhodopensis* leaves, with more stable stored  $S_{2(3)}Q_B^-$  charge pairs, are unsusceptible to DCMU, therefore, can possibly indicate some modifications of the redox properties of the quinone acceptor  $Q_B$  (especially in D1 core protein). In accordance with this suggestion are the data of Ohad et al. [44] and Hideg et al. [45], considering the observed incomplete suppression of the B band by DCMU after high light and UV-B irradiation as a proof for acceptor side modifications. Analogical deeper stabilization of  $S_{2(3)}Q_B^-$  charge recombination as a result of induced mutations in D1 protein have been also reported [46–49]. The already described specific lipid and sterol composition of *H. rhodopensis* leaves and the presence of different protective compounds in chloroplasts stroma may contribute to these modifications.

### 17.3.2 CHANGES IN THERMOLUMINESCENCE CHARACTERISTICS DURING DARK DESICCATION AND REHYDRATION

Under conditions of severe or prolonged water deficit, most plants are desiccation-intolerant (homoiohydric) and react to stress by the suspension of metabolism and irreversible damage to membrane structures and internal organization. Our data of changes in TL B band parameters from dehydrated spinach leaves [50] are in agreement with the respective desiccation sensitivity of this mesophytic plant. Severe dehydration of the leaves inhibits the number of operating centers, but leads predominantly to a well-expressed downshift of B band position close to Q band position. This observation is indicative for the destabilization of PSII centers as it was also shown in TL study on desiccating barley leaves [51]. It may be concluded that in mesophytic plants subjected to severe dehydration the electron transport between primary ( $Q_A$ ) and secondary ( $Q_B$ ) quinone acceptors is inhibited, and damaged oxygen-evolving complexes occur. Such PSII centers do not restore their photochemical activity during rehydration. Even more pronounced differences became in agreement with the results from Table 17.1, showing that damage sustained during dehydration become particularly detrimental after full metabolic activity have set in after spinach leaves rehydration.

The most important result emerging from TL studies of *H. rhodopensis* leaves is that severe dehydration of resurrection plants affects mainly the number of PSII reaction centers, judging from significant decrease of B band amplitude (Figure 17.4, left panels) without any changes in the energetic state of the remaining operative centers. After rehydration of desiccated *H. rhodopensis* leaves, the number and the oscillation pattern of operating PSII centers were nearly completely

**FIGURE 17.4** TL curves of fully hydrated, dehydrated, and rehydrated *Haberlea rhodopensis* leaves after excitation by one saturating flash without DCMU, or in the presence of 20  $\mu$ M DCMU (A, C, E). TL B band oscillations as a function of flash number for corresponding state of dehydration (B, D, F). Amplitudes were normalized at the second flash. The fully hydrated leaves were dehydrated in the dark to 60% RWC (A, B), 40% RWC (C, D), 20% RWC (E, F) and rehydrated in moist filter paper for 24 h. Leaf disks with a diameter of 10 mm were used in the experiments.

restored (Figure 17.4, right panels). This process was very rapid and rehydration for only 2 h restored more than 80% of the initial B band amplitude.

The effect of desiccation and subsequent rehydration on the redox functioning of PSII donor and acceptor side redox components of *H. rhodopensis* leaves was also assessed by the changes in the main TL bands emitted at illumination with continuous white light during cooling the leaf disks from room temperature to  $-20^{\circ}\text{C}$ . Under these experimental conditions a complex glow curve with well-resolved TL bands at about  $0^{\circ}\text{C}$  and  $45^{\circ}\text{C}$ , corresponding to Q and B bands [52] was obtained. Representative TL curve pattern from the leaves of fully hydrated *H. rhodopensis* plants is shown in Figure 17.5A.

The traces in Figure 17.5B and C reveal that increasing dehydration resulted in clear changes in the overall intensity of TL signals and redistribution of the TL emission between the existing Q and B bands with practically unchanged peak temperatures. In desiccated leaves, the amplitude of the TL B

band ( $S_{2(3)}Q_B^-$ ) sharply decreased and mainly a charge recombination related to  $S_2Q_A^-$  (Q-peak) takes place (Figure 17.5C). After rehydration TL glow curve pattern resembles that of the control (fully hydrated) leaves (Figure 17.5D), which means electron transport between the primary and secondary electron acceptors was reversibly modified. Analogical changes in the amplitude and oscillation pattern of the main TL B and Q bands, obtained during flash illumination [53], suppose that some changes in the kinetic characteristics of  $S_2$  and  $S_3$  states of PSII donor side during desiccation cannot be excluded.

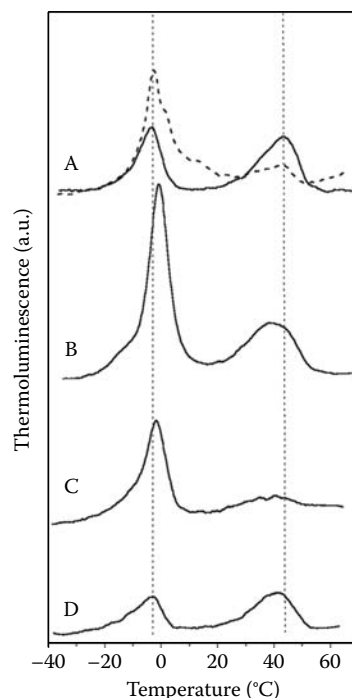

We suggested that the increased contribution of  $S_2Q_A^-$  charge recombination in dehydrated *H. rhodopensis* leaves served to protect  $Q_B$  site from over excitation. There are data that the increased population of  $Q_A^-$  enhances the probability for non-radiative energy dissipation and represents an effective mechanism of protection [48].

#### 17.4 PHOTOSYSTEM II REACTIONS IN CHLOROPLASTS MEMBRANES ISOLATED FROM FULLY HYDRATED AND DEHYDRATED *HABERLEA* *RHODOPENSIS* LEAVES

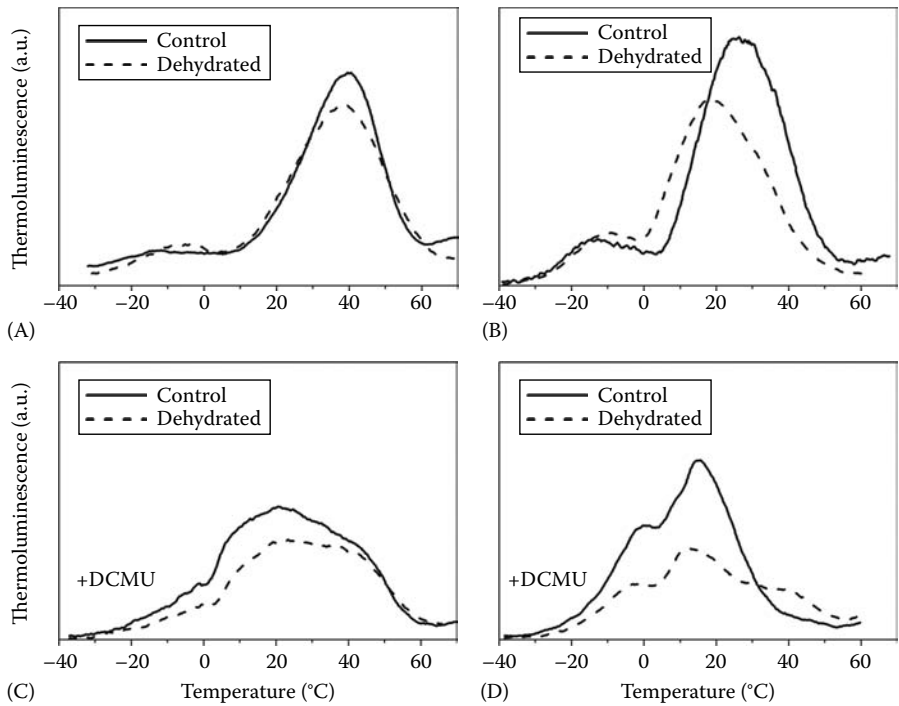

Answering the question whether the unique TL properties of the chlorophyll molecules of *H. rhodopensis* leaves were determined by some structural peculiarities required TL to be measured on isolated thylakoids. The obtained results show that the isolated photosynthesizing membranes from resurrection plant retain to a great extent the TL pattern of intact leaves thus indicating they were intrinsic features of PSII complex of *H. rhodopensis*.

The illumination of dark-adapted chloroplast suspensions isolated from fully hydrated *H. rhodopensis* leaves by continuous white light revealed a glow curve with a B band temperature maximum positioned at about 40°C (Figure 17.6A). The respective maximum in spinach chloroplast membranes appeared at much lower temperature of 26°C. The addition of DCMU to chloroplast suspension downshifted the B band emission maximum with formation of Q band at lower temperature (Figure 17.6C and D), but a residual B band like those in the leaves infiltrated with the electron-transport inhibitor was also observed, confirming the lower affinity of  $Q_B$  binding from PSII acceptor side in *H. rhodopensis* chloroplasts to DCMU.

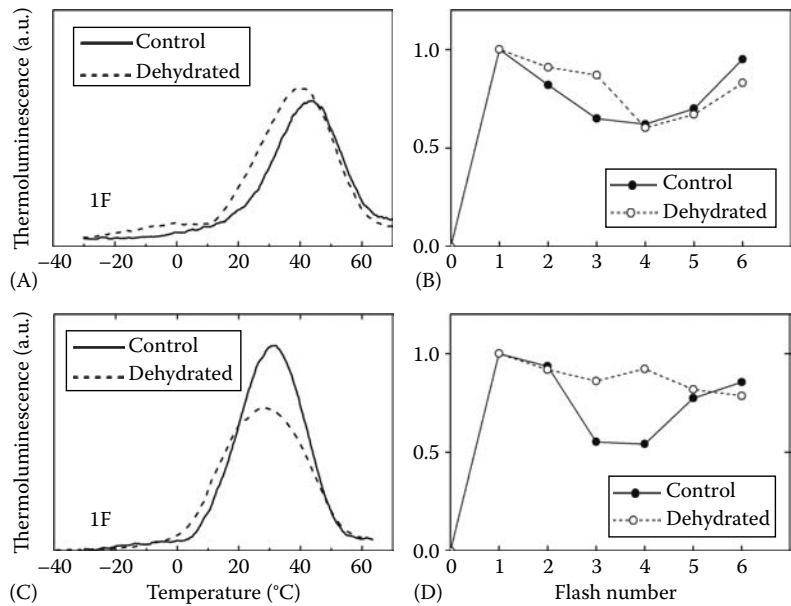

TL emission pattern of chloroplasts isolated from desiccated to 20% RWC *H. rhodopensis* leaves was identical to those isolated from fully hydrated plants (Figure 17.6A and C). The same maximal temperature position of B- and Q bands obtained in the both varieties of chloroplasts evidenced for a stable energetic state of recombination pairs, moreover, the reduction in overall TL intensity was found to be negligible. This is an indication that the chloroplasts isolated from desiccated leaves have been completely rehydrated when setting in resuspension medium and their functional activity was fully recovered in conformity with the preserved membrane integrity (Table 17.1). A significant downshift in temperature maximum and the decrease in the intensity of the respective TL bands in chloroplasts isolated from desiccated spinach leaves (Figure 17.6B and D) are a consequence of the membrane injuries occurred during severe stress.

**FIGURE 17.5** TL curves of *Haberlea rhodopensis* dark-adapted leaves after illumination by continuous white light of  $150 \mu\text{mol m}^{-2} \text{s}^{-1}$  from room temperature to  $-20^\circ\text{C}$  for 1 min. (A) Fully hydrated leaves 95% RWC and leaf disks infiltrated with  $20 \mu\text{M}$  DCMU (in dots). (B) Dehydrated leaves, 50% RWC. (C) Desiccated leaves, 10% RWC. (D) Rehydrated leaves for 24 h. Leaf disks with a diameter 10 mm were used in the experiments.

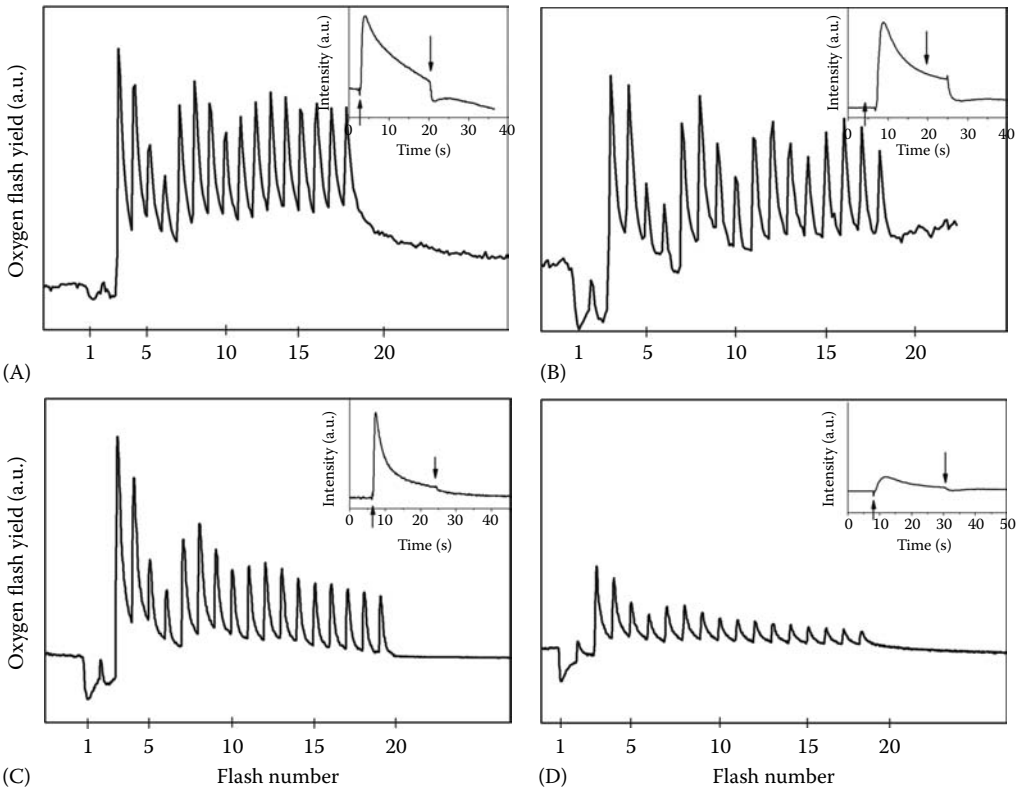

**FIGURE 17.6** TL emissions of *Haberlea rhodopensis* (A, C) and spinach (B, D) chloroplasts excited by continuous white light of  $150\mu\text{mol m}^{-2}\text{s}^{-1}$  at  $-20^\circ\text{C}$  for 1 min. The chloroplasts were isolated from fully hydrated leaves (solid lines) and leaves dehydrated to 20% RWC (dashed lines). Dark-adapted chloroplasts of  $1\text{ mg Chl mL}^{-1}$  were used in the experiments.

**FIGURE 17.7** TL B band of chloroplasts isolated from fully hydrated and dehydrated to 20% RWC leaves of *Haberlea rhodopensis* (A) and spinach (C) after excitation by one saturating flash. B band oscillations for *Haberlea rhodopensis* (B) and spinach (D) after excitation by flash sequences from 0 to 6. Amplitudes were normalized at the first flash. Dark-adapted chloroplasts of  $1\text{ mg Chl mL}^{-1}$  were used.

Changes in B band parameters (Figure 17.7A and C) and TL oscillation pattern (Figure 17.7B and D) of desiccated *H. rhodopensis* and spinach chloroplasts illuminated with saturated flashes compared to respective hydrated controls demonstrated once more that PSII reaction centers functioning was preserved in a great extent in resurrection plant.

Another reliable approach to study the properties of PSII complex in *H. rhodopensis* chloroplasts was to compare the kinetics of oxygen-evolving reactions with those of spinach membranes. The obtained results (Figure 17.8) demonstrated significant differences in the degree of inhibition of oxygen flash yields and the amplitude of initial oxygen burst between resurrection and mesophytic

**FIGURE 17.8** Oxygen flash yields sequences of chloroplasts isolated from fully hydrated (A) and dehydrated to 20% RWC (C) *Haberlea rhodopensis* leaves. Fully hydrated (B) and dehydrated to 20% RWC (D) spinach leaves. Insert: Oxygen evolution burst induced by 135 W m<sup>-2</sup> continuous white light. Dark-adapted chloroplasts of 0.3 mg Chl mL<sup>-1</sup> were used. The experiments were performed by a polarographic oxygen rate electrode with short (10 μs) saturating (4 J) flash sequences or continuous white light.

**TABLE 17.2**  
**Changes in the Kinetic Parameters of Oxygen-Evolving Reactions of Chloroplasts Isolated from Fully Hydrated and Desiccated *Haberlea rhodopensis* and Spinach Leaves, according to Kok's Model**

| Species         | RWC (%) | $S_0 + S_1$ (a.u.) | Misses ( $\alpha$ ) | Double Hits ( $\beta$ ) |
|-----------------|---------|--------------------|---------------------|-------------------------|
| <i>Haberlea</i> | 95      | 238.7 ± 6          | 0.151 ± 0.013       | 0.031 ± 0.004           |
| <i>Haberlea</i> | 20      | 213.1 ± 3          | 0.161 ± 0.008       | 0.027 ± 0.001           |
| Spinach         | 95      | 265.3 ± 11         | 0.137 ± 0.005       | 0.029 ± 0.002           |
| Spinach         | 20      | 54.2 ± 3           | 0.321 ± 0.008       | 0.020 ± 0.002           |

plants. The damping of oscillations of control chloroplasts and the chloroplasts, isolated from desiccated *H. rhodopensis* and spinach leaves was in accordance to the changes in the respective kinetic parameters, calculated by Kok's model [54]. As shown in Table 17.2, the desiccation of *H. rhodopensis* leaves do not change significantly the initial distribution of oxygen-evolving centers in  $S_0$  and  $S_1$  states and the values of misses ( $\alpha$ ) and double hits ( $\beta$ ). Alterations in the values of these parameters and in the shape of oxygen induction curve in desiccated spinach chloroplasts are indicative for membrane damage in the desiccation-intolerant plant.

## 17.5 CONCLUSION

The homoiochlorophyllous resurrection plant *Haberlea rhodopensis* Friv., demonstrated a deeper stabilization of PSII charge pairs, evidenced by an unusually high temperature maximum of the main TL B peak in the leaves and isolated thylakoid membranes. In addition, a part of these centers was less susceptible to DCMU, an inhibitor of electron transport. These features, as well as the strong reduction of the number of active PSII centers performing  $S_{2(3)}Q_B^-$  charge separation during desiccation without any changes in the energetics of the charge recombination in the rest operating centers were considered to indicate modifications of the redox properties of  $Q_B$ , related to desiccation tolerance of *H. rhodopensis*. It is reasonable to suggest that these modifications favor  $S_2Q_A^-$  charge recombination under desiccation. The increased population of  $Q_A^-$  enhances the probability for non-radiative energy dissipation and can represent an effective mechanism of protection during unfavorable environmental conditions.

## 18.1 INTRODUCTION

Carbohydrates are the most abundant compounds in living organisms. However, their importance does not purely rely in abundance, as they play key roles in cell functionality. In plants, carbohydrates are utilized for the synthesis of various structural components, and they are used to transport carbon and energy between tissues (Iglesias and Podestá 2005, Smith 1999). The central role of carbohydrates in the energetic metabolism is highlighted in the glycolytic and the oxidative pentose-P pathways. However, these pathways have another important role, as they serve as source of intermediates for the synthesis of a large number of cellular components, such as lipids, nucleic acids, organic acids, and proteins. Also, carbohydrates are fundamental components of structural molecules like cellulose, the most abundant biomolecule. In addition, sugars can be combined with other compounds, like lipids or proteins, to produce glycolipids and glycoproteins, which play key roles related with cell structure and function (Iglesias and Podestá 2005, Smith 1999). On the other hand, carbohydrates are the major reserve and mobilization constituents in plants, where they can be found as starch, sucrose, fructans, and polyols (Iglesias and Podestá 2005, Loescher and Everard 2004, Smith 1999).

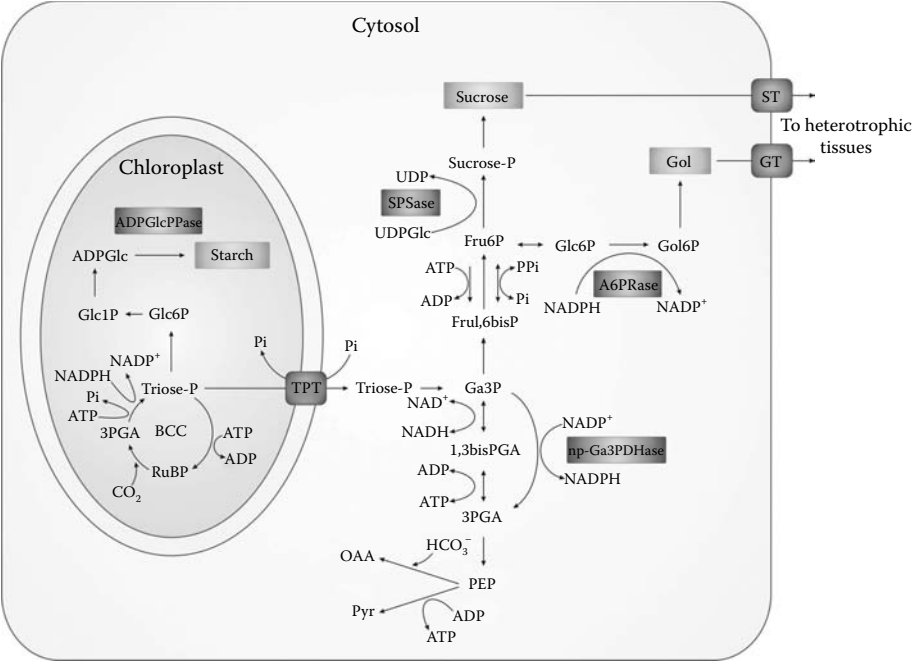

The sessile lifestyle of plants imposes severe challenges to their ability to survive in a changing environment. Plants are affected by a variety of stresses including, but not limited to, water shortage, nutrients deficiency, presence of toxic compounds (natural or arising from contamination), and temperature extremes. A series of mechanisms have been developed by plants that allow the adjustment of the metabolic machinery to cope with unfavorable conditions, which in fact may be the prevailing situation in the wild. Carbon metabolism contributes in various ways with the adaptation to a stressful situation. Relocation of carbon skeletons for the synthesis of specific stress-related metabolites, excretion of organic acids to confront the presence of toxic metals, or to minimize Pi deficiency or alterations in the main course of metabolic pathways through alternative routes are some of the responses observed. Metabolic adaptations include the transient adjustment of constitutive processes or the induction of latent ones to accommodate to a new condition by fine-tuning metabolism. More extensive changes can even include the adaptation of the whole photosynthetic mechanism of CO<sub>2</sub> assimilation as a result of a long-term challenge.

This chapter deals with the main adjustments of plant primary carbon metabolism to the most common forms of abiotic stress, which endow these organisms with the capacity to survive in a world of permanently changing situations. The outstanding role of carbohydrates for carbon and energy metabolism forces to highlight their involvement as key components of cellular processes. We analyze the different fates of carbohydrates produced by photosynthetic assimilation in plants. The analysis emphasizes on how metabolic routes mainly operating in the cytosol are critical to direct carbohydrate fluxes to produce energy, reduce power, and transport or reserve molecules. The overall picture seeks to understand relationship between carbohydrates and plant physiology, and the capacity to cope with different stress conditions.

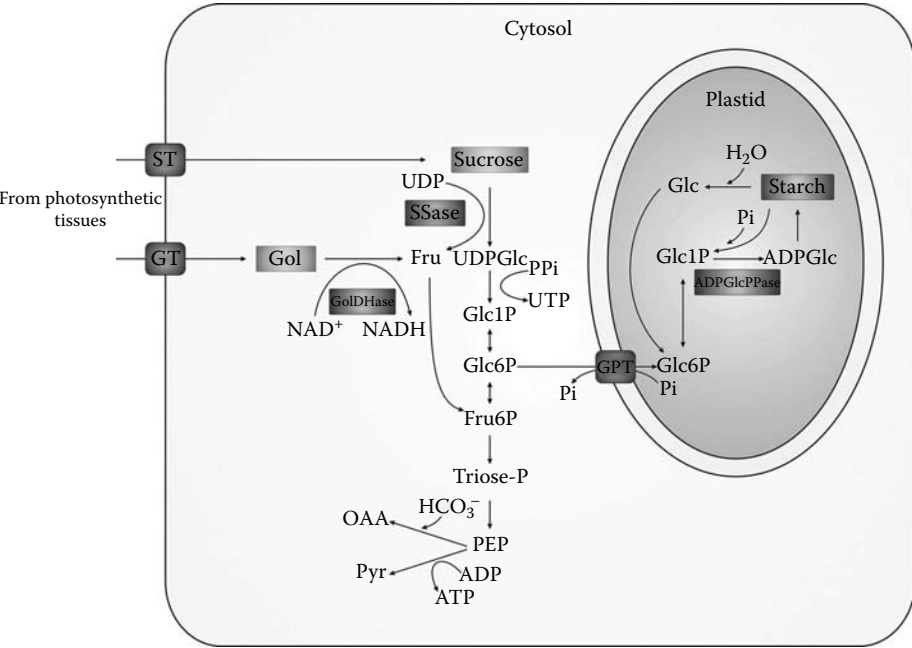

## 18.2 CARBON PARTITIONING IN PLANTS

Oxygenic photosynthesis is a process where the energy from light is utilized for carbohydrate production, thus playing a key role on Earth, because most organisms depend directly or indirectly on it to obtain energy. In the global photosynthetic process, the occurrence of two phases can be differentiated: (a) a light phase, where the electromagnetic sun energy is converted into chemical energy (ATP) and reducing power (NADPH) and (b) a synthetic phase, comprising the use of ATP and NADPH to fix atmospheric CO<sub>2</sub> to primarily generate carbohydrates. As shown in Figure 18.1, carbon fixation occurs in the chloroplast of the photosynthetic plant cell mainly through the Benson–Calvin cycle (BCC), utilizing ATP and NADPH produced in the light phase. This renders triose-P and hexose-P that can be used within chloroplasts for the production of starch. Alternatively, photosynthates (mainly in the form of triose-P) can be exported to the cytosol to be used in glycolytic routes as well as to synthesize sucrose or polyols, the major compounds used for carbon translocation from source to sink tissues. In this way, photoassimilates are subjected to two levels of partitioning. At the intracellular level, they are partitioned between the chloroplast and the cytosol, being triose-P the key intermediaries interexchanged with Pi through a specific translocator of the plastid envelope (TPT in Figure 18.1). In the cytosol, carbohydrates are derived to different routes, including glycolysis and synthesis of soluble sugars that are accumulated in this subcellular compartment and also utilized for transport to other parts of the plant through the phloem. In most plants, the major soluble sugar synthesized is sucrose, although many species also produce sugar-alcohols (e.g., glucitol, abbreviated Gol, see Figure 18.1) as a main metabolite. The second level of partitioning takes place as carbohydrates are distributed to other tissues having heterotrophic characteristics, being sucrose (or a sugar-alcohol in certain species) the main metabolite transported between different tissues. Once in the non-photosynthetic cell, sucrose (or the sugar-alcohol) is derived to different metabolic routes with the establishment, once again, of a partitioning of photoassimilates between the cytosol and the plastid (Figure 18.2).

As described above, carbohydrates are partitioned between a relatively stationary (starch) and a mobile (sucrose, polyols) form as major products of photosynthesis. It is important to understand the

**FIGURE 18.1** Schematic representation of carbon metabolism in plant photosynthetic cells. Key enzymes for carbon partitioning, the major photosynthetic products (starch, sucrose, and glucitol), and transporters (TPT, triose-P translocator; ST, sucrose transporter; GT, glucitol transporter) are highlighted. BCC is the abbreviation of Benson–Calvin cycle.

**FIGURE 18.2** Schematic representation of carbon metabolism in plant heterotrophic cells. Enzymes involved in sucrose, starch, and glucitol metabolism, photosynthates translocated from leaves (sucrose and glucitol), starch (the major storage compound), and the glucose-P translocator (GPT) are highlighted.

processes of synthesis, partition (within one cell and between source and sink tissues), and storage of carbohydrates because these molecules are crucial for plant productivity. The control of these processes is affected by different factors, at systemic or cellular levels, which may modify carbon and energy demands of different tissues (Iglesias and Podestá 2005). Starch biosynthesis takes place in the chloroplast (Figure 18.1) and involves three enzymatic steps, sequentially catalyzed by (see Equations 18.1 through 18.3, respectively, in Figure 18.3) ADP-glucose pyrophosphorylase (ADPGlcPPase, EC 2.7.7.27), starch synthase (EC 2.4.1.21), and branching enzyme (EC 2.4.1.18) (Ballicora et al. 2003, 2004). This polyglucan is the major storage compound in higher plants, and in photosynthetic and heterotrophic tissues. It has been established that starch constitutes a transitory storage glucan in source tissues and its level varies during the photoperiod; while the long-term storage occurs in the plastids of heterotrophic cells in non-photosynthetic tissues, such as fruits, roots, and tubers (Figure 18.2) (Iglesias and Podestá 2005).

**FIGURE 18.3** Key reactions catalyzed by enzymes involved in carbohydrate metabolism and partitioning in plants.

### 18.3 CARBON METABOLISM IN THE CYTOSOL AND PLANT STRESS

Many of the pathways of carbohydrate metabolism take place in the cytosol, where they are connected to other metabolic routes. In this compartment, there is a metabolic node constituted by fructose-6-P (Fru6P), glucose-6-P (Glc6P), and glucose-1-P (Glc1P). The conversion between Fru6P and Glc6P (see [Figure 18.3](#), Equation 18.4) is catalyzed by a hexose-P isomerase (EC 5.3.1.9) while the reaction that converts Glc6P into Glc1P (Equation 18.5 in [Figure 18.3](#)) is catalyzed by a phosphoglucomutase (EC 5.4.2.2). In plants, the hexose-P pool can be utilized to produce many other metabolites, thus directing carbon skeletons to different metabolic fluxes (Smith 1999). The main fates for cytosolic hexose-P include glycolysis and synthesis of soluble sugars as sucrose and polyols. These central metabolic routes produce intermediate metabolites or final products that play critical roles in plants under physiological as well as stress conditions.

#### 18.3.1 ORGANIZATION OF PLANT GLYCOLYSIS

Glycolysis is a ubiquitous metabolic pathway that converts glucose (Glc) into pyruvate (Pyr) in most organisms, producing 2 ATPs as a result (Givan 1999, Plaxton 1996, Podestá 2004). Glycolysis is just the first step of respiration, the fundamental process of intermediary metabolism. In plants, glycolysis is unique in that it possesses a series of differential features and its function goes beyond the provision of ATP and Pyr for mitochondrial respiration (Plaxton and Podestá 2006). One of these characteristics is the ability to use PPi instead of ATP as phosphoryl donor (Plaxton and Podestá 2006, Stitt 1998). Also, ancillary enzymes can be found that expand the classic 10 reactions pathway and lend a great degree of flexibility to metabolism (Plaxton 1996). Most important, the final product of cytosolic plant glycolysis is not necessarily Pyr. Instead, the cytosolic pool of phosphoenolpyruvate (PEP) represents a metabolic branch point from which carbon skeletons may follow different fates (Plaxton 1996, Plaxton and Podestá 2006). In addition, Glc is not the obligated starting metabolite for glycolysis: the photosynthetically generated hexose-P or triose-P pools can both contribute with carbon skeletons in the route toward PEP or Pyr (Dennis and Blakeley 2000). Finally, it must be mentioned that plants possess a second set of glycolytic enzymes in the plastid, with its own distinctive characteristics. All of these features can be efficiently exploited by plants to face different types of stress situations.

Starting from the top, down along the conventional glycolytic pathway, the first distinguishing characteristic of the plant cell cytosolic glycolytic metabolism arises at the level of the conversion of Fru6P to Fru1,6bisP. As in most other organisms, it is a key regulatory step, but the phosphorylation reaction can be achieved by two different enzymes (see, respectively, Equations 18.6 and 18.7 in [Figure 18.3](#)): a classical but Fru2,6bisP-insensitive ATP-dependent phosphofructokinase (ATP-PFKase, EC 2.7.1.11) or a PPi-dependent enzyme that uses PPi as phosphoryl donor (PPi-PFKase, EC 2.7.1.90) and is potently activated by Fru2,6bisP (Carnal and Black 1979, Dennis and Blakeley 2000, Givan 1999, Iglesias and Podestá 2005, Plaxton and Podestá 2006) ([Figure 18.1](#)). Plant PPi-PFKase is widespread in different plant species and tissues and its subunit composition and activity respond to environmental and developmental cues (Nielsen 1995, Plaxton and Podestá 2006, Podestá and Plaxton 1994a, Theodorou and Plaxton 1996, Trípodí and Podestá 1997). Current knowledge indicates that it most probably works in the glycolytic direction, despite the fact that it catalyzes a reversible reaction, controlling the balance between the triose-P and hexose-P pools and carbon partitioning among starch and sucrose (Hajirezaei et al. 1994, Plaxton 1996, Plaxton and Podestá 2006, Podestá and Plaxton 2003).

Following conversion of Fru1,6bisP into triose-P, the first energy-conserving reaction takes place with the generation of ATP by the joint action of glyceraldehyde 3-P dehydrogenase (Ga3PDHase, EC 1.2.1.12) and phosphoglycerate kinase (EC 2.7.2.3). The first reaction (Equation 18.8 in [Figure 18.3](#)), the only oxidation that takes place during glycolysis, can be circumvented by a NADP-dependent, non-phosphorylating glyceraldehyde 3-P dehydrogenase (np-Ga3PDHase, EC 1.2.1.9)

that yields 3PGA and uses NADP rather than NAD as acceptor of the reducing equivalents (Bustos and Iglesias 2002, Iglesias et al. 2002) (see [Figure 18.3](#), Equation 18.9). The reaction is irreversible in this case, and leads to a product that cannot be used to generate ATP. The contribution of this enzyme thus leads to a nil ATP yield. However, the importance of np-Ga3PDHase in plant cytosolic metabolism is beginning to be acknowledged, having been implicated in fruit development and energetic metabolism. A recent work (Bustos et al. 2008) points out that the np-enzyme is implicated in the response to oxidative stress in wheat leaves. Also, plants deficient in this enzyme were found to exhibit a reduced glycolytic capacity and increased levels of oxidative stress (Rius et al. 2006).

From then on, two reactions lead to the production of PEP. As stated above, PEP occupies a central role in plant carbohydrate metabolism as a regulatory molecule, but it is also significant as a branchpoint metabolite. PEP is the substrate for a carboxylation reaction (see [Figure 18.3](#), Equation 18.10), mediated by PEP carboxylase (EC 4.1.1.31), a regulatory enzyme that produces oxaloacetate (OAA) and Pi (Chollet et al. 1996, Iglesias et al. 1997) ([Figure 18.1](#)). PEP carboxylase exists in various isoforms and different levels in plant tissues. It plays a major role in anapleurosis replenishing intermediates of the tricarboxylic acid pathway, and thus links cytosolic carbon metabolism with respiration and N assimilation. In  $C_4$  and Crassulacean acid metabolism plants the enzyme is responsible for the primary  $CO_2$  fixation, starting the  $CO_2$  concentrating mechanism. PEP carboxylase is subjected to tight regulation by metabolites and by reversible phosphorylation on a serine residue (Bakrim et al. 2001, Chollet et al. 1996, Trípodí and Plaxton 2005). Malate is a strong inhibitor of PEP carboxylase, but its effect is dependent on pH and, most important, on the phosphorylation status of the enzyme. The phosphorylated form of PEP carboxylase is usually more active and less sensitive to malate, specially at pH values on the acidic side of the optimum, which is around pH 8.0 (Baur et al. 1992, Chollet et al. 1996, Hartwell et al. 1999, Moraes and Plaxton 2000, Trípodí and Plaxton 2005). Glc6P is an important allosteric effector, promoting activation of the enzyme and reducing malate sensitivity (Chollet et al. 1996, Plaxton 1996). The enzyme from  $C_3$  plants (i.e., banana fruit and castor bean germinating endosperm) is very sensitive to inhibition by aspartate and glutamate, highlighting the link between N and C metabolism mediated by PEP carboxylase (Law and Plaxton 1995, Trípodí and Plaxton 2005). Phosphorylation alleviates the effect of aspartate (Gregory et al. 2009, Law and Plaxton 1995, Trípodí and Plaxton 2005). The characterization of PEP carboxylase kinase has shown that its ability to phosphorylate the target enzyme is impaired in the presence of malate, while it performs better in the presence of PEP (Murmu and Plaxton 2007).

PEP is also the substrate for the usual end of glycolysis in most organisms, the reaction catalyzed by Pyr kinase (PyrKase, EC 2.7.1.40) that produces Pyr and ATP (see [Figure 18.3](#), Equation 18.11) and constitutes the second energy-conserving reaction. PyrKase has been studied in many plant tissues where its regulatory role of the whole glycolytic process has been recognized (Hu and Plaxton 1996, Lin et al. 1989, Moraes and Plaxton 2000, Plaxton 1989, Podestá and Plaxton 1991). In fact, the activity of this enzyme is instrumental in controlling the flux of the upper part of glycolysis by regulating the levels of PEP (Givan 1999, Plaxton 1996), as it will be further analyzed below. PyrKase regulation is organ specific in plants. The cytosolic PyrKase from germinating castor seed endosperm or cotyledons shows a pH-dependent response to several metabolite inhibitors (Podestá and Plaxton 1991, Podestá and Plaxton 1994b). A concerted decrease in pH and inhibitor concentrations, as could be caused by anoxia, will cause PyrKase activity to rise. Glutamate is an important inhibitor of the enzyme from several sources (Hu and Plaxton 1996, Lin et al. 1989, Plaxton 1996, Plaxton and Podestá 2006, Podestá and Plaxton 1994b), while aspartate activates PyrKase and relieves from the inhibitory effect of the former. The reciprocal effects of aspartate on PyrKase and PEP carboxylase provide an effective mechanism to balance both activities during active N assimilation. Thus, aspartate accumulation reduces the flux through PEP carboxylase while enhancing PyrKase activity in leaves, ripening banana fruit and castor bean endosperm (Plaxton and Podestá 2006, Smith et al. 2000, Turner et al. 2005, Turner and Plaxton 2000).

A third enzyme also makes use of PEP. PEP carboxykinase (PEPCKase, EC 4.1.1.49) catalyzes the reversible carboxylation of PEP, using ADP as substrate as well, to yield OAA and ATP (Chen et al. 2004, Daley et al. 1977, Leegood and Walker 2003, Rylott et al. 2003, Walker and Leegood 1996, Wingler et al. 1999) (Figure 18.3, Equation 18.12). Although generally implicated in gluconeogenesis, the activity of PEPCKase is also crucial to determine the concentration of PEP. It has been shown that the enzyme is subjected to phosphorylation in many but not all plants (Leegood and Walker 2003). The study of PEPCKase has been hindered by the extreme sensitivity of the enzyme to proteolysis upon extraction (Martín et al. 2007). The truncated, but otherwise active enzyme exhibits few, if any, regulatory properties. The phosphorylation site lies within the excised peptide, which strongly suggest that whatever changes in the regulation of PEPCKase are brought about by phosphorylation are not evident on the proteolyzed enzyme (Leegood and Walker 2003). So far, studies with a preparation containing only the phospho or dephospho forms of PEPCKase are lacking, but the use of special reaction media designed to measure preferentially one form demonstrated that phosphorylation lowers PEPCKase activity (Leegood and Walker 2003). A strict coordination in the phosphorylation status of PEP carboxylase and PEPCKase is necessary as the two enzymes acting at the same time can give rise to a potential futile cycle.

Levels of PEP thus depend on the coordination of the activities of at least three regulatory enzymes. The importance of this can be appreciated after examination of the role of PEP as a regulatory metabolite. In plants, the conversion of Fru6P to Fru1,6bisP does not represent the primary control point of glycolysis, in part due to the lack of activation of ATP-PFKase by Fru2,6bisP. PPI-PFKase, instead, is strongly activated by Fru2,6bisP (Kruger and Dennis 1987, Theodorou and Plaxton 1994, Trípodi and Podestá 1997). To date, all plant cytosolic ATP-PFKases examined are inhibited by PEP (Givan 1999, Lee and Copeland 1996), and this metabolite also is an inhibitor of the synthesis of Fru2,6bisP (Plaxton and Podestá 2006). Levels of PEP, thus, control the flux through the upper part of glycolysis, reinforcing the role of PEP carboxylase and PyrKase as pacemaker enzymes of the whole pathway. This does not mean that control is completely delegated on these two enzymes; rather that the primary control depends on them. ATP-PFKase and PPI-PFKase are still relevant for the fine-tuning of carbon flow in the cytosol, with activities that depend on the levels of PEP but also on Pi concentration, as Pi activates ATP-PFKase while it is a powerful inhibitor of the glycolytic reaction of PPI-PFKase (Plaxton and Podestá 2006, Podestá 2004). In any case, the study of the contribution of ATP-PFKase, PPI-PFKase, PEP carboxylase, and PyrKase by the use of transgenic lines deficient in or overexpressing these enzymes is complicated by the great degree of metabolic flexibility that plants show. In many cases, successful creation of a transgenic plant does not result in an evident phenotype, or it displays it only under a particular condition (Grodzinski et al. 1999, Hajirezaei et al. 1994, Stitt and Sonnewald 1995).

### 18.3.2 METABOLISM OF SUCROSE AND POLYOLS

In leaves, during the light period, sucrose is produced from triose-P translocated from the chloroplast through the TPT in exchange for Pi (Figure 18.1). In the dark, starch mobilization allows the constant production of sucrose and the uninterrupted flow of carbon to heterotrophic tissues (Winter and Huber 2000). The reactions that derive to sucrose synthesis include the action of sucrose-P synthase (SPSase, EC 2.4.1.14) and sucrose-P phosphatase (EC 3.1.3.24) (see Figure 18.1, and Equations 18.13 and 18.14 in Figure 18.3). Sucrose is then transported to sink tissues where its degradation can be catalyzed by two different classes of enzymes. Invertases (EC 3.2.1.26, Equation 18.15 in Figure 18.3) catalyze the irreversible hydrolysis of sucrose to Glc and Fru. On the other hand, a reversible cleavage of sucrose occurs by the action of sucrose synthase (SSase, EC 2.4.1.13, Equation 18.16 in Figure 18.3; see also Figure 18.2) (Iglesias and Podestá 2005, Winter and Huber 2000). The latter reaction conserves the energy of the glycosidic bond in UDP-glucose (UDPGlc), which can be used for cellulose synthesis or can enter glycolysis. In heterotrophic tissues, Glc6P or Glc1P are the preferred molecules carried

through a specific translocator (GPT, see [Figure 18.2](#)) inside plastids, where it can be utilized for starch synthesis (Winter and Huber 2000).

In addition to sucrose and starch, certain plants synthesize Gol (also known as sorbitol) or mannitol as important photosynthetic products (Loescher and Everard 2004). In these organisms, the analysis of [ $^{14}\text{C}$ ]CO<sub>2</sub> assimilation reveals the presence of two major soluble compounds: the polyol and sucrose. In apple leaves, about 70% of the newly photosynthetically fixed carbon was found as Gol and sucrose (Grant and Rees 1981). In celery, almost 80% of the label in mature leaves was recovered as mannitol and sucrose, with similar quantities (on a molar basis) of each one (Loescher et al. 1992). Similar results were obtained in apricot, where Gol was found to be the compound with the highest label 30 min after the pulse (Bielecki and Redgwell 1977). Gol is a major photosynthetic product in many important fruit-bearing tree species of the Rosaceae family, such as apple, peach, pear, and loquat. In general, a few studies deal with sugar-alcohols metabolism, in particular if compared with the abundant bibliography concerning starch (Ballicora et al. 2003, 2004) and sucrose (Koch 2004, Winter and Huber 2000) pathways. Because in many plants sugar-alcohols are main photosynthetic products, their metabolism is expected to be tightly regulated, probably at different levels. It is worth noting that sugar-alcohols could have important roles in plant tolerance to certain types of abiotic stresses (Loescher and Everard 2004).

Gol is synthesized in mature leaves through the conversion of Glc6P into Gol6P by the action of a NADPH-dependent aldose-6-phosphate reductase (A6PRase, EC 1.1.1.200; see Equation 18.17 in [Figure 18.3](#)) (Figuerola and Iglesias 2010, Hirai 1981, Kanayama and Yamaki 1993, Zhou et al. 2003b) and the subsequent hydrolysis of the phosphate group catalyzed by a specific Gol6P phosphatase (EC 3.1.3.50, Equation 18.18 in [Figure 18.3](#)) (Zhou et al. 2003a). These enzymes can be found in the cytosol in soluble forms, without any association with vacuoles, chloroplasts, mitochondria, peroxysomes, or membranes (Loescher and Everard 2004). The NADPH necessary for synthesizing the sugar-alcohol may be derived from the reaction catalyzed by np-Ga3PDHase (see [Figure 18.3](#), Equation 18.9), which has been found in celery leaves at levels capable of sustaining relevant production of mannitol by this plant (Gao and Loescher 2000, Rumpho et al. 1983). The sugar-alcohol produced in leaves can be transported to sink or developing tissues, such as fruits or immature leaves, where it can be converted to Fru by the action of a NAD-dependent Gol dehydrogenase (GolDHase, EC 1.1.1.14, Equation 18.19 in [Figure 18.3](#)) (Ohta et al. 2005, Oura et al. 2000, Yamaguchi et al. 1994).

## 18.4 PLANTS CARBOHYDRATE METABOLISM AND STRESS

### 18.4.1 RESPONSES OF GLYCOLYTIC CARBON METABOLISM ENZYMES TO STRESS

#### 18.4.1.1 Hexose-P Metabolism

Mertens et al. (1990) found that PPI-PFKase (but, not ATP-PFKase) is induced upon anoxia in rice seedlings. Fru2,6bisP also increases during anoxia in rice seedlings, helping to boost PPI-PFKase activity in a more acidic environment that could curtail this enzyme's activity (Mertens 1990). In this tissue, sucrose degradation proceeds mainly through the uridylate requiring the sucrose synthase/nucleoside diphosphate kinase system, lowering the dependence on adenylates that usually have lower levels upon this condition (Ricard et al. 1991). Pi starvation increases PPI-PFKase levels in *Brassica nigra* and *Brassica napus* (Theodorou and Plaxton 1994, 1996). *B. nigra* seedlings respond to Pi starvation by increasing the extractable activity of PPI-PFKase, the ratio PPI-PFKase:ATP-PFKase and by an increase in the amount of the  $\alpha$  relative to the  $\beta$  subunit (Theodorou and Plaxton 1994). The same response in the  $\alpha$ : $\beta$  ratio has been observed in black mustard suspension cells under Pi deficit (Theodorou et al. 1992). In both cases, the sensitivity to Fru2,6bisP is increased. Thus, the response to Pi stress at the hexose-P pool level is clearly to circumvent the adenylate-dependent step catalyzed by ATP-PFKase. This is a result of the acquired ability of plants to use PPI as a phosphoryl donor, efficiently using the energy available in the anhydride bond

(Stitt 1998). Assuming that PPi is a by-product of anabolism; no ATP is needed for the conversion of sucrose to hexose-P via the SSase pathway in heterotrophic tissues, whereas 2 ATPs are needed for the invertase pathway. Remarkably, although PPi can be hardly conceived as nothing more than a transient by-product of several cell reactions, which is readily hydrolyzed in animal cells, PPi levels in the cytosol of plant cells remain stable through a variety of conditions, including, but not limited to, severe Pi-deficiency or anoxia, which is consistent with the importance of PPi-dependent enzymes during stress (Plaxton and Podestá 2006, Stitt 1998). The importance of PPi in plant cell economy has been demonstrated by the creation of transgenic plants expressing a bacterial pyrophosphatase in the cytosol. These plants showed a threefold decreased PPi concentration and also severely impaired growth (Jellito et al. 1992).

The link between Pi nutritional status and the regulation of ATP-PFKase and PPi-PFKase is also evident from the fact that ATP-PFKase is regulated by the Pi:PEP ratio (with Pi being an activator and PEP an inhibitor); while Pi is a potent inhibitor of PPi-PFKase in the glycolytic direction (Dennis and Blakeley 2000). This suggests that under Pi deficiency, the latter would be the predominant activity, thus allowing an adenylate-independent glycolytic pathway. Pi-PFKase has been implicated in the response to cold stress as well. An examination of the subunit composition of PPi-PFKase in orange fruits showed a displacement of the  $\alpha:\beta$  subunit ratio from 1.66 to 1 upon exposure to frost and almost a doubling of its activity, all this complemented by an increased sensitivity to Fru2,6bisP (Falcone Ferreyra et al. 2006). Cold stress leads to an initial fall in sucrose synthesis, accumulation of phosphorylated metabolites, and consequent Pi-limitation of photosynthesis (Stitt and Hurry 2002). Plants respond to the challenge by increasing sucrose synthesis. Within minutes of initiation the cold stress in *Arabidopsis thaliana*, SPSase is posttranslationally activated by phosphorylation (Stitt and Hurry 2002). On the longer term, SPSase and cytosolic Fru1,6bisP phosphatase expression are boosted, releasing the Pi necessary for sustained photosynthesis at the expense of phosphorylated metabolites (Stitt and Hurry 2002). The response also includes movement of Pi from the vacuole to the cytosol, to allow the replenishment of phosphorylated metabolites without depleting free Pi (Hurry et al. 2000). Thus, as expressed by Stitt and Hurry (2002): “changes in Pi modulate and may even act as a signal in the regulation of photosynthetic/metabolic acclimation to low temperatures, and lead to major changes in the ability of the different genotypes to develop frost tolerance.”

#### 18.4.1.2 PEP Metabolism

Levels of PEP carboxylase have been reported to vary in response to different abiotic stresses. Recently, a study in frost-damaged orange fruits showed increased levels of PEP carboxylase in stressed fruit, which correlate with a lower sensitivity to its natural feedback inhibitor malate (Falcone Ferreyra et al. 2006). Since the fermentative pathway is higher in this tissue, it has been proposed that PEP carboxylase could act, in combination with malate dehydrogenase, as an ancillary fermentative enzyme, helping in the provision of ATP when aerobic respiration is affected (Falcone Ferreyra et al. 2006). Vu et al. (1995) reported that cold-hardy citrus varieties responded with an increase in extractable PEP carboxylase activity upon acclimation, whereas a sensitive cultivar showed a decrease in foliar PEP carboxylase levels. Similar trends have been reported in other cultivars exposed to cold (Vu et al. 1995), underscoring an as yet little studied role of PEP carboxylase in plant primary metabolism. Abiotic stresses that affect water balance, including cold stress and anoxia, also provoke an induction of PEP carboxylase. Induction was root-specific, except for the cold treatment, which also induced the enzyme in shoots (González et al. 2003). In general, induction of PEP carboxylase has been linked to an increased need for synthesis of organic acids such as malate, in response to cytoplasmic alkalization among other challenges.

PEP carboxylase activity is also responsive to Pi levels. Several studies showed an increase in PEP carboxylase content upon nutritional deprivation of Pi. One of the first papers describing the bypass of adenylate-using enzymes upon Pi deprivation in *B. nigra* suspension cells reported that PEP carboxylase, np-Ga3PDHase, PPi-PFKase, and PEP phosphatase showed important increases

in activity at the expense of the ATP-PFKase, PyrKase, and Ga3PDHase (Duff et al. 1989). *B. napus* efficiently uses rock Pi by excreting organic acids to the environment with the concurrent solubilization of the former. Pi deprivation in *B. napus* and the related hedge mustard caused an increase in PEP carboxylase levels and, probably as a result of this, also in malate exudation (Hoffland et al. 1992). Moraes and Plaxton (2000) reported the purification and properties of the Pi-deficient *B. nigra* PEP carboxylase. Pi starvation increased PEP carboxylase by 2.5-fold, while refeeding caused an immediate return to near control levels. The study of the purified enzyme showed that the increased activity under Pi shortage cannot be attributed to an increased phosphorylation state of the enzyme that would make it less susceptible to malate inhibition. It is possible that, at least in these cells, metabolite effects override the importance of phosphorylation in PEP carboxylase control (Moraes and Plaxton 2000). Several reports (Andaluz et al. 2009, Thimm et al. 2001) highlight the induction of PEP carboxylase in roots under iron deficiency. The induction of PEP carboxylase accompanies the apoplastic acidification caused by iron starvation (Thimm et al. 2001). PEP carboxylase induction in roots is paralleled by increased levels of several glycolytic enzymes, namely, Ga3PDHase, phosphoglyceromutase, enolase, and PyrKase. This, together with an enhanced mitochondrial electron transport complement, reveals a respiratory surge as a response to iron stress.

#### 18.4.2 SOLUBLE CARBOHYDRATES AND THEIR ROLE AGAINST STRESS

Many organisms accumulate low molecular weight compounds such as disaccharides (sucrose and trehalose), sugar-alcohols, quaternary amines, or amino acids. It has been proposed that these molecules allow organisms tolerate certain kinds of abiotic stresses (like salinity, cold or drought) through mass action. These compounds may be considered as compatible solutes, a term that was introduced in studies conducted with yeast accumulating nonreducing sugars (like trehalose) and sugar-alcohols (including glycerol) in response to osmotic stress (Brown and Simpson 1972). It is well known that different inorganic ( $K^+$ ,  $Na^+$ ,  $Cl^-$ , and  $SO_4^{2-}$ ) and organic (reducing hexoses) molecules are critical to establish osmotic adjustments in aqueous systems. However, these compounds are different from compatible solutes, which may affect the properties of solutions by distinctive ways (Bohnert and Jensen 1996, Loescher and Everard 2004). Early work established that high concentrations of compatible solutes do not interfere with *in vitro* enzyme activities and that sometimes they can protect proteins from deleterious effects of salts or heat (Bohnert and Jensen 1996, Loescher and Everard 2004). It has been described that the concentration of these molecules should reach values as high as 500 mM to exert protection; interestingly, such levels may be achieved in cells (Moing et al. 1997, Nadwodnik and Lohaus 2008).

Different explanations have been proposed to clarify the protective effect of compatible solutes on biological structures. One hypothesis is that they substitute water molecules in the hydration of proteins and membranes, thus allowing enzyme activity to occur even at extremely low water concentrations (Webb and Bhorjee 1968). Another alternative suggests that compatible solutes might be outside the hydration sphere of proteins, thus producing a particular rearrangement of the sphere and inducing the biological structure to adopt a preferential hydration (Timasheff 1993). Concerning plants, studies performed at the present time highly support the possibility to derivate cytosolic carbohydrates to different metabolic fates rendering compounds of the type of compatible solutes. Accumulation of these metabolites could help the plant to resist extreme conditions of low temperatures, high salt levels, and water deficit. The overall picture sustain that modifications in the balance of photosynthates partitioning can play critical roles for plant productivity and survival under physiological or stress conditions.

##### 18.4.2.1 Osmotic Stress Adaptation

Plants response to osmotic stress generally results in increased soluble sugars and decreased starch as a result of enhanced sugar synthesis. This rise in carbohydrates concentration has been related with higher activity levels of the synthesizing enzymes. For instance, SPSase activity dramatically increased in osmotically stressed spinach leaves and potato tubers. This activation is consequence of the phosphorylation of a single residue (serine-424 in spinach leaf SPSase), and is different from that involved

in dark-light modulation (Winter and Huber 2000). This site is widely conserved among species and its phosphorylation in osmotically stressed leaves activates the enzyme, thus allowing sucrose synthesis to occur when it would otherwise be restricted (Toroser and Huber 1997). Accumulation of sucrose, cyclic, or acyclic sugar-alcohols, proline, and quaternary amines (like glycinebetaine) could potentially play a direct role in osmoregulation and could also provide quickly metabolizable carbohydrates for energy production when carbon is diverted from growth to other functions (Hare et al. 1998).

#### 18.4.2.2 Low-Temperature Stress

Carbohydrates such as sucrose, fructans, and sugar-alcohols can be important in tolerance and resistance to cold-induced damage (del Viso et al. 2009a,b, Loescher and Everard 2004, Pontis 1989, Tognetti et al. 1990). Cold damage results by desiccation due to water demand from the protoplast, as a consequence of the growing ice crystal (Loescher and Everard 2004). Even when results are not conclusive, many studies have related this kind of stress with the accumulation of compatible solutes. For instance, it was found that Gol concentration in apple shoot xylem increased with leaf senescence and low temperatures (Williams and Raese 1974). Similar changes have been described in plum trees, where the highest level of Gol in sap was found after exposing plants to temperatures below zero (Loescher et al. 1990). Further evidence in the same way was obtained by Hirai (1983), who reported a raise of Gol and A6PRase levels in loquat leaves during low-temperature seasons. In addition, accumulation of sucrose in photosynthetic and heterotrophic tissues has been linked with increased SPSase activity under nonfreezing temperatures, which was related to an increased level of SPSase protein in spinach leaves (Guy et al. 1992) and potato tubers (Hill et al. 1996). In spinach leaves, the rate of SPSase protein synthesis seems to be responsible for the raise in activity and the newly produced enzyme subunit appears to be identical to that found under normal conditions (Guy et al. 1992). On the other hand, cold-exposed potato tubers showed an increase in a particular subunit (1b) of SPSase, which correlates with a change in the kinetic properties of this enzyme. Thus, the altered kinetics of SPSase may play an important role in the regulation of sucrose synthesis in cold-stored tubers (Hill et al. 1996).

#### 18.4.2.3 Drought Stress

Results relating drought stress and carbohydrates accumulation are difficult to understand as a result of secondary effects, like growth inhibition and dehydration (Loescher and Everard 2004). However, it is important to draw attention to the evidences. For instance, Gol was the main soluble carbohydrate and its content was doubled in plants from the *Prunus* genus subjected to drought stress (Ranney et al. 1991). In apple trees, drought stress resulted in the preferential accumulation of Gol and Glc at the expense of sucrose and starch (Wang et al. 1995, 1996). When genetically transformed plants were used, it was demonstrated that the increased ability for synthesizing soluble sugar-alcohols promoted drought tolerance. In transformed tobacco plants synthesizing the nonreducing disaccharide trehalose, it was determined that their ability to survive after a drought period was enhanced. However, their phenotypes were altered and the growing rate was diminished up to 50% under normal growing conditions (Holmstrom et al. 1996). A similar work, where transformed tobacco plants were engineered to produce bacterial fructans, showed that these plants grew better than controls under polyethyleneglycol-induced drought, conditions where the growing rates and the fresh and dry weights were also higher. On the other hand, compared with those plants producing trehalose, these transformed plants did not show differences with controls under normal conditions (Pilon-Smits et al. 1995).

#### 18.4.2.4 High-Salinity-Induced Stress

The correlation between salt stress and sugars accumulation is quite strong, and these works represent the most numerous reports linking one type of stress with polyols accumulation. A couple of studies, done with celery exposed to NaCl-induced stress (Everard et al. 1994) or macronutrients excess (Stoop and Pharr 1994) established that changes in mannitol metabolism were consequence of both carbon partitioning and utilization. For instance, in newly developed celery leaves exposed to 300 mM NaCl, the carbon flux into mannitol remained at similar rates to controls, although a 70%

decrease in carbon assimilation was found. The maintenance of mannitol synthesis was at sucrose expenses, thus increasing fourfold the ratio between mannitol and sucrose labeled. This change was associated to an increase in the activity of mannose-6-P reductase (EC 1.1.1.224). However, this increase in activity was not related to a rise in the protein level of the enzyme, suggesting a possible posttranslational modification of the enzyme (Everard et al. 1994). On the other hand, a study conducted with Japanese persimmon (*Diospyros kaki*, a plant that normally does not produce sugar-alcohols) transformed with the gene encoding for the A6PRase from apple leaves, found an increase in tolerance to NaCl-induced stress in those lines capable of accumulating Gol (Gao et al. 2001).

#### 18.4.2.5 Hydroxyl-Radical Scavengers

Reduced stomatal conductance can occur under salt and drought stress, thus increasing the production of free radicals. There is evidence that in fungi and other organisms sugar-alcohols (such as Gol and mannitol) and cyclic polyols (like *mio*-inositol) can act as free radical scavengers (Jennings and Burke 1990, Smirnoff and Cumbes 1989). Also, it was shown that this effect could be observed in stress caused by dehydration (Smirnoff 1993). However, the evidence of *in vivo* assays is limited. For instance, transformation of tobacco plants with a bacterial mannitol-1-P dehydrogenase (EC 1.1.1.17), directed to chloroplasts by the introduction of a transit peptide, rendered a line capable of accumulating mannitol in chloroplasts in concentrations up to 100 mM, with no alteration of the phenotype or the photosynthetic activity. The presence of mannitol in chloroplasts resulted in an increased tolerance to methylviologen, a compound that produces oxidative stress. It is important to emphasize that the presence of the polyol did not reduce the abundance of reactive oxygen species, but it conferred an additional protection to the already present in non-transformed plants (Shen et al. 1997).

### 18.5 CONCLUDING REMARKS

As can be inferred from the numerous examples listed above, carbon metabolism and partitioning critically affect plant productivity under physiological and stress conditions. Thus, the understanding of key enzymes involved in different metabolic routes operating in plants is relevant to evaluate potential plant adaptation in different environments. Many factors can affect the expression pattern of genes and the activity of enzymes related to carbohydrates metabolism. In general, the modulation of enzyme activity by metabolites (allosterism) or posttranslational modifications (thiols oxidation and reduction or phosphorylation) have been relatively well established in sucrose and starch biosynthetic pathways. On the other hand, the enzymes involved in sugar-alcohols metabolism have been scarcely characterized. Thus, efforts should be made to develop accurate systems to express and purify these enzymes, and such a work is currently under way (Figueroa and Iglesias 2010, Ohta et al. 2005). Developing molecular tools to identify the functionality of different enzymes and to rationally modify plant metabolism is promissory to handle plant behavior in diverse habitats.

## 19.1 INTRODUCTION

Environmental stresses present major challenges in our quest to achieve sustainable food production. The reactions of plants to environmental stresses are complex and involve a wide array of physiological and biochemical responses. Such responses are initiated by plants growing in stressed environments to overcome, avoid, or nullify the effects of stresses. Tolerance or sensitivity toward a particular stressful condition depends on the genetic and biochemical makeup of the species. Much attention has been focused during recent years to evolve crop species with adaptability built into their genetic and biochemical makeup to withstand various stressful environmental conditions.

Plants are unable to express their full genetic potential for production when subjected to stressful environments (Zeigler, 1990; Gao et al., 2007). When exposed to stressed environments, plants initially recognize the stress stimulus, and thereafter a signal transduction cascade is

invoked. Secondary messengers relay the signal, activating stress-responsive genes, the expression of which causes the accumulation or depletion of certain metabolites, alteration in the activity behaviors of many enzymes, overall changes in protein synthesis, and, of particular interest, synthesis of new sets of proteins that are specific to the particular type of stress (Jacobsen et al., 1986; Vierling, 1991; Kaur and Gupta, 2005; Sharma and Dubey, 2007; Kumar et al., 2008; Gupta et al., 2009). It has been shown that different environmental stresses induce the synthesis of novel proteins in plants, which possibly provide evolutionary value to the plants for enhanced survival in adverse environmental situations. The synthesis of such stress-induced proteins has been well documented under salinity stress (Ericson and Alfinito, 1984; Hurkman and Tanaka, 1987; Singh et al., 1987; Ben-Hayyim et al., 1989; Naot et al., 1995; Naqvi et al., 1995; Igarashi et al., 1997; Aarati et al., 2003; Mahmoodzadeh, 2009), osmotic stress or drought (Bewley and Larsen, 1982; Singh et al., 1987; Vance et al., 1990; Robertson and Chandler, 1994; Baker et al., 1995; Mantyla et al., 1995; Perezmolphebalch et al., 1996; Zhang et al., 1996; Jiang and Huang, 2002; Demirevska et al., 2008; Khurana et al., 2008), heat shock (Heikkila et al., 1984; Mansfield and Key, 1988; Vierling, 1991; Cordewener et al., 1995; Waters et al., 1996; Lee et al., 2007; Yildiz and Terzi, 2008), low-temperature treatment (Meza-Basso et al., 1986; Hahn and Walbot, 1989; Bruggemann et al., 1994; Griffith et al., 1997; Matsuba et al., 1997; John et al., 2009; Kikuchi and Masuda, 2009), anaerobiosis (Ricard et al., 1991; Christopher and Good, 1996; Sachs et al., 1996; Subbaiah and Sachs, 2003), infection with pathogens (Antoniw et al., 1980; Ohashi and Matsuoka, 1985; Abad et al., 1996; Herbers et al., 1996; Tornero et al., 1997; Almagro et al., 2009), wounding (Cabello et al., 1994; Jung et al., 1995; Schaller and Ryan, 1996; Jimenez et al., 2008; Dafoe et al., 2009), metal toxicity (Choi et al., 1995; Shah and Dubey, 1998a; Sharma and Dubey, 2007), gaseous pollutants (Kirtikara and Talbot, 1996), and ultraviolet (UV) radiation (Jung et al., 1995; Rao et al., 1996; Xu et al., 2008; Pan et al., 2009). Figure 19.1 shows the schematic diagram of synthesis of proteins under different stresses in plants. These proteins, which are stress specific, present newer avenues to improve stress tolerance of plants.

The main idea underlying studies of stress-induced synthesis of proteins in plants is that the different sources of stresses, their duration, and severity lead to a differential expression of genetic

**FIGURE 19.1** Stress-induced protein synthesis in plants. Stresses cause important modifications in the gene expression in plants, which leads to the synthesis and accumulation of stress-related proteins. These proteins provide enhanced survival value to plants under adverse environmental situations and can be used to produce stress-tolerant plants by genetic transformations. For details, refer Section 19.2.

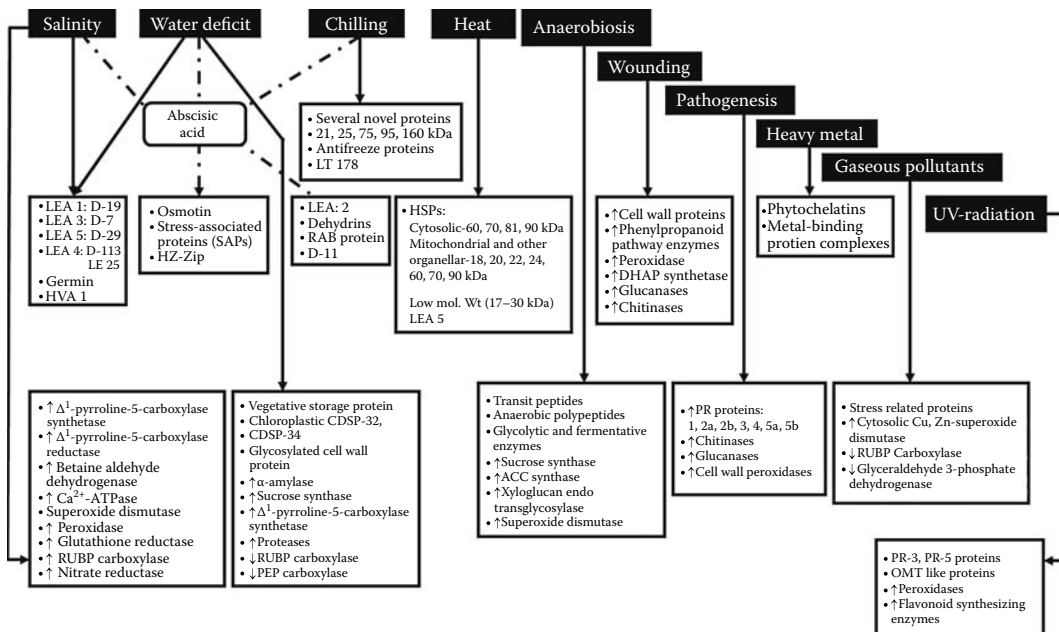

information, resulting in changes in gene products, including mRNA and proteins. Such newly synthesized proteins are specific to the particular type of stress and possibly confer enhanced survival value to the plants (Ben-Hayyim et al., 1989). Stress-induced proteins identified from different organs of plants have been well characterized. Physicochemical parameters such as molecular weight and pI (isoelectric point) values of these proteins have been deduced (Ben-Hayyim et al., 1989; Robertson and Chandler, 1994; Sachs et al., 1996; Waters et al., 1996; Efeoglu and Terzioglu, 2007), and, in many cases, data regarding association characteristics and amino acid sequences have also been reported (Singh et al., 1987; Badur et al., 1994; Naot et al., 1995; Zhang et al., 1996). A sizeable volume of literature indicates quantitative and qualitative changes in proteins, when plants are stressed, mainly employing the methods of electrophoresis, the western analysis, enzyme kinetics studies, etc. Nowadays, high-throughput stress-induced protein identification and characterization systems using tools of proteomics are available. Improved protein extraction and purification protocols have been devised, and genomic sequence databases for peptide mass matches are available (Timperio et al., 2008). Although the stress proteins are synthesized in plants when they are subjected to stresses and can be revealed in tissues of plants adapted to stress, specific metabolic functions for most of these proteins have not been established as to how they confer adaptability toward stress (Ben-Hayyim et al., 1989; Artlip and Funkhouser, 1995; Khurana et al., 2008). Particularly, under anaerobic stress, the polypeptides that are synthesized have specific functions and belong to the enzymes of sugar phosphate metabolism (Ricard et al., 1991). Heat-shock proteins (HSPs), which are synthesized under heat stress, possibly assist in protein folding, protein-protein interactions, and the translocation of proteins across cellular compartments, and they have a possible role in protecting the organism from heat stress (Cordewener et al., 1995; Wang et al., 2004). Similarly, the pathogenesis-related (PR) proteins do act in the defense of the plants and have a putative role in pathogen resistance (Artlip and Funkhouser, 1995). Under salinity stress, it is suggested that the newly synthesized proteins, together with amino acids and soluble nitrogenous compounds, act as components of a salt-tolerance mechanism. These might function as compatible cytoplasmic solutes in osmotic adjustment in order to equalize the osmotic potential of the cytoplasm with the vacuoles in adverse conditions of salinity (Greenway and Munns, 1980; Dubey and Rani, 1989).

Studies related to stress-induced synthesis of proteins have been performed using cultured plant cells (Ericson and Alfinito, 1984; Singh et al., 1987; Ben-Hayyim et al., 1989; Vance et al., 1990; Sobkowiak and Deckert, 2006), seedlings (Mansfield and Key, 1988; Hahn and Walbot, 1989; Han and Kermode, 1996; Igarashi et al., 1997; Efeoglu and Terzioglu, 2007), excised plant organs (Hurkman and Tanaka, 1987; Stuiver et al., 1988), and intact plants (Burke et al., 1985; Ohashi and Matsuoka, 1985; Kee and Nobel, 1986; Popova et al., 1995). Among these systems, cultured plant cells have proven to be superior to other systems as they show uniform response and are under better control of environmental parameters (Ben-Hayyim et al., 1989; Fadzilla et al., 1997). Cell cultures from tobacco, cowpea, potato, citrus, and many other plant species have been used to identify and characterize newly synthesized proteins under salinity, heat-shock, freezing, osmotic, and heavy metal stresses (Singh et al., 1987; Ben-Hayyim et al., 1989; Vierling, 1991; Naot et al., 1995; Fadzilla et al., 1997). During recent years, a wealth of literature has been available, dealing with environmental stress-induced proteome changes, based on whole tissue/organ analysis (Bae et al., 2003; Giacomelli et al., 2006; Goulas et al., 2006; Taylor et al., 2009). Taylor and coworkers (2009) analyzed data and reviewed a collection of both whole tissue and organellar proteomic studies that investigated the effects of environmental stress in the model plant *Arabidopsis thaliana*. They found 279 proteins that could change in abundance and could be assigned as protein components of the energy organelles (chloroplast, mitochondria, and peroxisomes). These could be placed into eight different functional categories, and nearly 80% of the specific protein isoforms detected were only reported to change in a single environmental stress.

Besides, the identification of specific-stress-induced proteins, several investigators have tried to quantify the overall metabolic status of total and soluble proteins (including enzymes) of different metabolic pathways in stressed plant parts in order to evaluate the impact of stresses on various aspects

of plant growth and metabolism (Dubey and Rani, 1987; Dubey and Rani, 1989; Gogorcena et al., 1995; Shah and Dubey, 1995a,b; Jha and Dubey, 2004a,b; Mishra and Dubey, 2006, 2008a,b; Sharma and Dubey, 2007; Maheshwari and Dubey, 2007, 2008, 2009). Environmental stresses generally are detrimental to plant growth, adversely affect the metabolism of plants, and cause an imbalance in the level of protein as a result of their effects on the synthesis and hydrolysis of proteins (Dubey and Rani, 1987; Elsamad and Shaddad, 1997; Moons et al., 1997; Shah and Dubey, 1998a,b; Mishra and Dubey, 2006; Maheshwari and Dubey, 2007, 2008). Abiotic stresses lead to an enhanced degradation of proteins. Amino acids derived from protein catabolism may be redistributed within the plant via the phloem and serve as a basis for protein synthesis in other plant parts (Feller et al., 2008). In salt- and drought-stressed plant parts, the protein content decreases owing to the decreased rate of protein synthesis and the increased rate of proteolysis (Dubey and Rani, 1987, 1990; Perezmolphebaltch et al., 1996; Sharma and Dubey, 2005a). In seeds germinating under salinity, moisture stress, or nickel toxicity, however, an increase in the protein level is observed. This increase can best be explained by the fact that in germinating seeds, stress causes decreased proteolysis in endosperms, resulting in a slower depletion of reserve proteins. This reflects an apparent increase in the endospermic protein level under stress, which is not a result of enhanced protein synthesis (Dubey, 1983a; Dubey and Rani, 1987, 1990; Maheshwari and Dubey, 2008). Salt tolerance is dependent on the genetic and biochemical characteristics of the species. Therefore, attempts have been made by certain groups of investigators to differentiate stress-tolerant and stress-sensitive genotypes of crops on the basis of profiles or levels of soluble proteins, specific enzymes in germinating seeds, and growing plant parts (Dubey and Rani, 1987, 1989; Perezmolphebaltch et al., 1996; Elsamad and Shaddad, 1997; Mahmoodzadeh, 2009). The results of these attempts indicate that different levels of soluble proteins and many enzymes exist in the two sets of genotypes differing in stress tolerance.

Studies conducted so far indicate that stressful conditions adversely affect the protein metabolism in plants and that in all different types of environmental stresses, such as salinity, drought, heat, chilling, anaerobiosis, pathogenesis, wounding, heavy metal toxicity, and gaseous

**FIGURE 19.2** An overview of stress-induced protein-synthetic responses in plants. Different stresses induce the synthesis of various groups of proteins and cause either elevation (↑) or decline (↓) in the levels of enzymes. Some of the responses of salinity, drought, and chilling are common and are mediated via elevated levels of ABA. For details, refer Section 19.1.

pollutants, new stress-specific proteins are synthesized. These proteins might play a role in signal transduction, antioxidative defense, antifreezing, heat shock, metal binding, anti-pathogenesis, or osmolyte synthesis (Qureshi et al., 2007; Timperio et al., 2008). Recent developments in sensitivity and accuracy for proteome analysis have provided new dimensions in identifying novel proteins and in assessing the changes in protein types and their expression levels under stresses (Qureshi et al., 2007). An overview of protein-synthetic responses in plants and alterations in the levels of key enzymes under various stresses is presented in Figure 19.2. These proteins that have been discussed in detail in Section 19.2 can be successfully used as attractive targets to produce stress-tolerant plants using biotechnological approaches (Table 19.1). The identification of novel stress-responsive proteins provides not only new insights into stress responses but also a good starting point for further dissection of their functions (Yan et al., 2006), and opens up new avenues for the production of stress-tolerant plants using traditional breeding or transgenic approaches. This chapter presents our current status of knowledge related to the effect of various environmental stresses on the overall aspects of protein synthesis in plants, and the possible role of stress-specific proteins in conferring an enhanced survival value to the plants against various environmental stress situations.

## 19.2 STRESSED ENVIRONMENTS AND PROTEIN SYNTHESIS

The major type of stresses to which plants are exposed include salinity, drought, flood, heat, cold, anaerobiosis, infection by pathogens, metal toxicity, gaseous pollutants, and UV radiation. Plant metabolism and, more specifically, protein synthesis are adversely affected under these conditions. The effect of stress depends on the developmental stage of the plant, genotypes of the plant species, as well as the intensity and duration of the stress. The progress achieved so far in our understanding of the impact of different environmental stresses on protein synthesis is described in Sections 19.2.1 through 19.2.10.

### 19.2.1 SALINITY

Soil salinity is a major environmental stress that drastically affects crop productivity. Salinity poses a severe threat for the cultivation of crops in arid and semiarid regions of the world. Due to the continuous buildup of salinity in the soil, millions of hectares of usable land have now become unsuitable for cultivation. It is estimated that every year more than a million hectares of land is subjected to salinization. Soil salinity is thus threatening the civilization by persistently reducing the area for crop cultivation. Salinity not only causes great losses in crop yields but also has an impact on other economic, environmental, social, and political problems in the affected countries. The progress in developing salt-tolerant crop varieties has been very slow due to our incomplete knowledge of the mechanism of salt damage and the complex nature of salt tolerance. Even different varieties of a particular species may exhibit different tolerance behaviors. Salinity affects seed germination, plant growth, nutrient uptake, and metabolism owing to osmotic inhibition of water availability, ion imbalance, toxic effects of salt ions, and their effects on cellular gene expression machinery (Dubey and Pessarakli, 1995; Abdelkader et al., 2007). Different plant species have developed different mechanisms to cope up with salinity stress effects (Munns, 2002; Abdelkader et al., 2007). Salinity promotes the synthesis of salt stress-specific proteins (Hurkman and Tanaka, 1987; Singh et al., 1987; Ben-Hayyim et al., 1989; Artlip and Funkhouser, 1995; Mahmoodzadeh, 2009); causes either decreases (Popova et al., 1995) or increases (Dubey, 1983a; Elenany, 1997) in the level of total and/or soluble proteins, depending on the plant parts studied; and leads to increased activity/synthesis of many enzymes (Dubey and Rani, 1987, 1990; Dubey et al., 1987; Mittal and Dubey, 1991, 1995; Igarashi et al., 1997).

#### 19.2.1.1 Salt-Induced Protein Synthesis

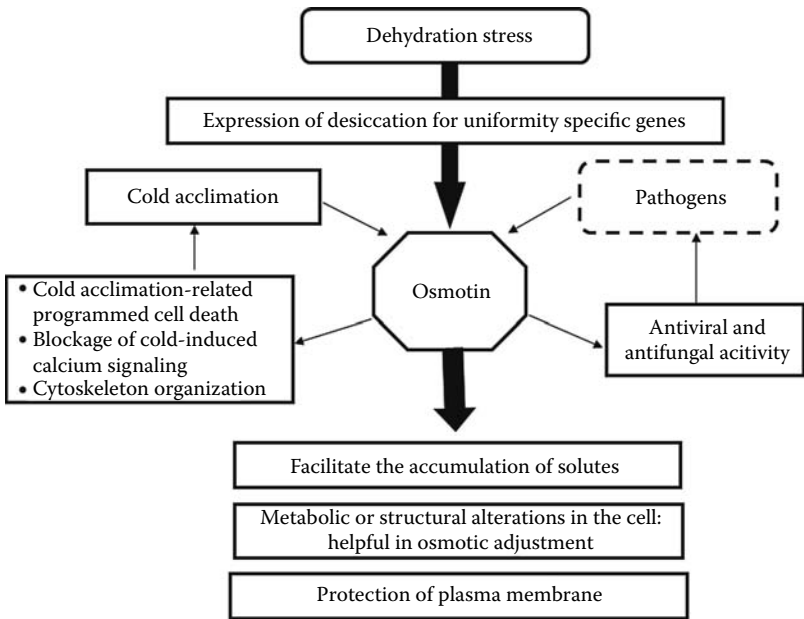

Plants growing in a saline environment show distinct changes in the pattern of synthesis and accumulation of proteins. Most of the experiments to study the salinity-induced synthesis of proteins have been conducted using plant cell cultures. Cell cultures rather than whole plant systems have proven to be more advantageous for such studies, because, in cell cultures, environmental parameters can be better controlled and the stress-tolerant cell lines generated can be readily selected and assayed for newly synthesized proteins.

Several investigators have shown the synthesis of new proteins in cultured plant cells when subjected to salinity stress (Ericson and Alfinito, 1984; Singh et al., 1987; Ben-Hayyim et al., 1989; Artlip and Funkhouser, 1995; Elenany, 1997). The level of proteins differs in salt-tolerant and salt-sensitive genotypes when they are subjected to salinity stress (Dubey and Rani, 1989; Elsamad and Shaddad, 1997; Mahmoodzadeh, 2009; Tada and Kashimura, 2009). Although it is well established that salt tolerance and sensitivity depend on the genetic and biochemical compositions of the species, it has been difficult so far to specify the exact genetic domain responsible for salt-adaptation expression leading to the synthesis of these proteins in salt-adapted plants. These specifically synthesized proteins under salt stress appear to have a role in providing tolerance or adaptation to the plants. However, the overall mechanism of how these proteins could provide adaptation is not clearly understood.

To understand the mechanism of salt resistance in cultured tobacco cells, Ericson and Alfinito (1984) examined the protein patterns of NaCl-adapted as well as NaCl-nonadapted cell lines of tobacco (*Nicotiana tabacum* L.). Their results indicated that cells adapted to a medium containing NaCl showed two protein bands of 32 and 20 kDa in more abundance than unadapted cells. Further, in the salt-adapted cells, a unique protein of 26 kDa appeared that was specific for these cells and was not present in unadapted cells or cells growing without NaCl. These investigators suggested that the three proteins synthesized in salt-adapted cells might be involved in a salt-adaptation process. Yildiz (2007) observed the synthesis of two new low-molecular-weight (LMW) proteins (28.9 and 30.0 kDa) and one intermediate-molecular-weight (IMW) protein (44.3 kDa) in response to the NaCl treatment in wheat cv. Ceyhan-99 (salt sensitive), whereas six LMW proteins (18.6, 19.4, 25.7, 25.9, 26.0, and 27.6 kDa) were newly synthesized in wheat cv. Firat-93 (salt tolerant). The newly synthesized proteins were specific to each cultivar. Most of the newly synthesized proteins were acidic in nature with mol. wt. <31.6 kDa. These newly synthesized proteins were suggested to be important for cultivars differing in sensitivity toward NaCl (Yildiz, 2007).

According to Singh et al. (1985), in cultured tobacco cells, the process of cellular adaptation to osmotic stress in a saline environment involves the specific alteration in the gene expression of salt-adapted cells, leading to the synthesis of several novel proteins, including the predominant 26 kDa protein. Since the 26 kDa protein is specifically synthesized and accumulated in cells undergoing an osmotic adjustment to salt or dessication stress, this protein has been named “osmotin” (Singh et al., 1987). Plant cells undergoing dessication stress specifically synthesize and accumulate osmotin, which provides the osmotic adjustment to the cell. Osmotin also plays a role in cold acclimation (CA) and in response against viral and fungal pathogen infections (Figure 19.3). Osmotin is regarded as a unique protein associated with NaCl-adapted tobacco cells (Singh et al., 1987). Interestingly, the synthesis of osmotin is not induced by osmotic shock but starts only when cells are adapted to NaCl or polyethylene glycol (PEG) (Singh et al., 1985). In salt-adapted cells, osmotin constitutes about 10%–12% of the total protein content in the cell (Singh et al., 1985). Tada and Kashimura (2009) observed an increased osmotin content at early time points following salt treatment in lateral

**FIGURE 19.3** Plant cells undergoing dessication stress specifically synthesize and accumulate osmotin, which helps in providing osmotic adjustment to the cell. Osmotin also plays a role in CA and against viral and fungal pathogen infections.

roots of the mangrove plant *Bruguiera gymnorhiza*, and concluded that osmotin may play a role in the initial osmotic adaptation in lateral roots of *B. gymnorhiza* under salt stress, but does not contribute toward adaptation to prolonged or continuous exposure to salt stress. A primary role played by osmotin during low water potential conditions appears to be as a protectant of the plant plasma membranes (PMs) (Singh et al., 1989).

It is believed that osmotin plays the role of providing an osmotic adjustment to the cells either by facilitating the accumulation of solutes or by providing certain metabolic or structural alterations in the cell, which may be helpful in osmotic adjustment (Singh et al., 1987). Although some understanding of the possible mechanism underlying the defense function of osmotin against biotic stresses is beginning to emerge, its role in stress response is far from clear (Parkhi et al., 2009). Protective abilities of osmotin against salinity stress have been confirmed by overexpression studies. The constitutive expression of an osmotin gene in transgenic tobacco was found to improve its tolerance to salinity (Barthakur et al., 2001). Improved germination of seeds and higher growth rates of plants under high salinity were observed in transgenic strawberry expressing tobacco osmotin (Husaini and Abdin, 2008).

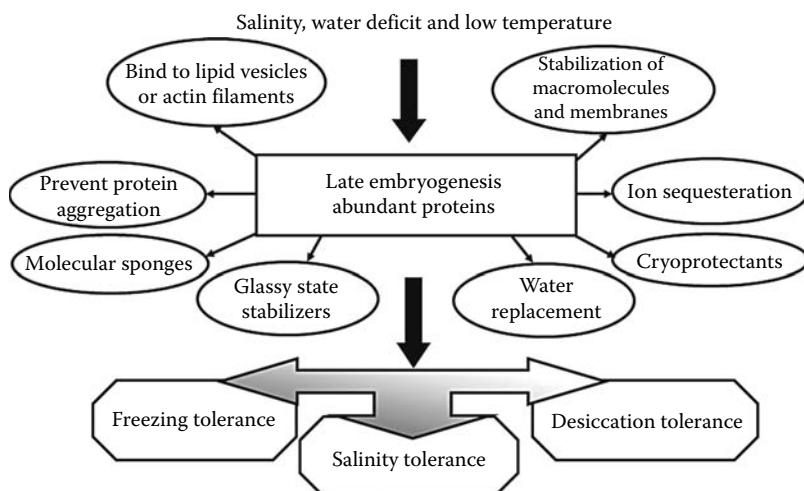

Similar to tobacco cells, the synthesis of salt-induced proteins has also been shown in barley (Hurkman and Tanaka, 1987; Popova et al., 1995), maize (Ramagopal, 1986), citrus (Ben-Hayyim et al., 1989; Naot et al., 1995), rice (Naqvi et al., 1995), and finger millet (Uma et al., 1995). Barley plants, when subjected to a short-term NaCl shock or a long-term NaCl treatment for a period of 8 days show marked quantitative and qualitative changes in protein profiles compared to nonstressed plants (Hurkman and Tanaka, 1987; Popova et al., 1995). The maize callus tissue (Ramagopal, 1986) shows predominantly the accumulation of a 26 kDa protein under saline stress. In potato plants, high salinity leads to an increased synthesis of 32 and 34 kDa proteins in the thylakoids (Pruvot et al., 1996). A comparison of the protein profiles of nonadapted and NaCl-adapted cell lines of citrus and tomato indicates that, in citrus, the level of most proteins is suppressed, whereas, in tomato, it is enhanced under salt stress (Ben-Hayyim et al., 1989). Tomato cell cultures when grown in a medium with 25 mM NaCl and proline, synthesize extra polypeptides of 190, 58, 45, and 26 kDa, and with the further increase of NaCl in the medium, a new 67 kDa protein gets accumulated (Elenany, 1997). In tobacco cells, an enhancement in the level of certain proteins and a decrease in the level of others are observed when cells are adapted to NaCl (Singh et al., 1987). This indicates that salt-induced changes in proteins are species specific and that different proteins are associated with salt tolerance in different species. Using germinating seeds of broad bean (*Vicia faba*) lines, Ahmed and coworkers (2001) showed that salinity stress caused an increase in the number of protein bands in bean line 67 (salt tolerant), whereas no considerable effect of salinity stress on the protein patterns could be observed in bean line 13 (salt sensitive).

An electrophoretic analysis (sodium dodecyl sulfate-polyacrylamide gel electrophoresis [SDS-PAGE]) of total soluble protein profiles of canola salt-tolerant cv. Okapi and salt-sensitive cv. Symbol in response to salt stress showed induction in the synthesis of few polypeptides in seeds. The number of induced proteins was greater in the tolerant cultivar than in the sensitive. These differences could be associated with the biochemical adjustment of the plants to cope up with the saline conditions (Mahmoodzadeh, 2009). In certain plant species, such as rice (*Oryza sativa* L.) and Shamouti orange (*Citrus sinensis* L. Osbeck), it has been shown that salt-sensitive and salt-tolerant genotypes have different patterns of protein profiles whether grown in the absence or the presence of NaCl. Salt-tolerant genotypes of rice possess a 28 kDa protein in shoots, which is absent in salt-sensitive genotypes, and the level of this protein is further elevated when the rice seedlings are raised in a saline medium (Rani, 1988). This shows that the presence of the additional 28 kDa protein band is associated with salt-tolerance characteristics in rice. In salt-sensitive rice species, some of the major preexisting proteins disappear and certain new proteins appear with an increase in salinity. Ten-day-old seedlings of rice cv. Nonabokra, Basmati, IR 28, and IR 29 when treated with 2% NaCl for 8 h show a synthesis of two new proteins of 27.0 and 25.5 kDa (Naqvi et al., 1995), whereas the seedlings of certain rice cultivars when exposed to salinity stress accumulate 87 and

85 kDa stress-associated proteins (SAPs) (Pareek et al., 1997). Similar to rice, in citrus (*C. sinensis* L. Osbeck), a 25 kDa protein has been shown to be associated with salt tolerance (Ben-Hayyim et al., 1989). This protein appears to be a constitutive protein in salt-tolerant citrus cells and is present whether cells are grown in the absence or the presence of NaCl. The level of this protein is enhanced when cells are grown in a saline medium. An enhancement can be readily observed by growing the cells in a growth medium containing 1% NaCl.

Since the synthesis of constitutive proteins associated with salt tolerance in rice or citrus does not depend on the presence of salt in the growth medium, it appears that the salt-tolerance trait is stable in these species. Salt-tolerant lines in these species show a synthesis of such constitutive proteins up to many generations when grown either in the presence or in the absence of NaCl. Similar constitutive proteins have also been shown to be associated with sensitive or tolerant genotypes of finger millet. Among finger millet (*Eleusine coracana* Gaertn.) genotypes differing in tolerance to NaCl, a 200 mM the NaCl treatment causes the synthesis of many stress-induced proteins with molecular weights of 70–72, 52, 37, 24, and 23 kDa in all genotypes. But in the tolerant genotype GE-415, the synthesis of a 54 kDa protein occurs under a NaCl treatment, which is not observed in the salt-sensitive genotype VL-481 (Uma et al., 1995). This suggests that the synthesis of NaCl-induced proteins in finger millet is correlated with the differences in the salt tolerance of the genotypes. In a species of citrus, either in cell suspension or when seedlings are grown in the presence of 0.2 M NaCl, the steady-state level of a citrus-LEA5 (C-LEA5) protein increases (Naot et al., 1995). Proteome analysis has allowed the identification of several novel proteins that are synthesized in plants in response to salinity (Tada and Kashimura, 2009; Yang et al., 2009). Yang and coworkers (2009) identified 38 salt-responsive proteins in the leaves of *Populus cathayana* Rehder by the peptide mass fingerprint (PMF) analysis. Some of the novel salt-responsive proteins identified were suggested to be involved in physiological and biochemical responses to salt stress in *P. cathayana*. A novel salt-responsive protein, not previously detected by the expressed sequence tag analysis or the transcriptome analysis, was identified in the mangrove plant *B. gymnorhiza* using comparative two-dimensional electrophoresis, which may provide insight into the salt-tolerance mechanism of the mangrove plant (Tada and Kashimura, 2009).

In many plant species, certain hydrophilic proteins and their mRNAs have been reported to be synthesized *de novo* in response to salt stress. Some of these proteins and mRNAs are also induced by a water deficit treatment with abscisic acid (ABA) (Artlip and Funkhouser, 1995). Such proteins have been grouped in different classes based on DNA sequences of their genes and/or predicted functions of the proteins (Bray, 1995). In most of the cases, the functions of the inducible protein have not been clearly established, and predicted functions have been proposed based on deduced amino acid sequences (Bray, 1995). Salinity imposition during the period of seed development following maturation leads to the synthesis of late embryogenesis-abundant (LEA) proteins in cotton, carrot, barley, and maize (Ramagopal, 1993). The LEA proteins contribute to salinity tolerance, desiccation tolerance, and freezing tolerance in plants by playing roles in ion sequestration, water replacement, and stabilization of macromolecules and membranes. The LEA proteins can act *in vitro* as glassy-state stabilizers, cryoprotectants, and molecular sponges; prevent protein aggregation; and bind to lipid vesicles or actin filaments (Figure 19.4). In vegetative organs of many other plant species, salinity-induced proteins that share significant amino acid sequences with the LEA proteins of cotton have been identified. Thus, various groups of LEA proteins have been identified, which have been classified based on notable structural domains predicted by amino acid sequences (Bray, 1995). LEA group 1 proteins include the Em family of proteins, which are devoid of cysteine and tryptophan. Such proteins have been identified in many monocots and dicots, and it is suggested that these proteins function in a water-binding capacity creating a protective aqueous environment (Bray, 1995). In salt-treated finger millet seedlings, a 21 kDa protein belonging to LEA group 1 of proteins appeared as the most prominent, whereas cucumber, a salinity-sensitive species, did not show any detectable level of expression of this protein when exposed to salt stress. The relatively tolerant species, such as finger millet and proso millet, showed higher levels of expression

**FIGURE 19.4** Roles of LEA proteins in freezing tolerance, salinity tolerance, and desiccation tolerance. Functions of LEA proteins in water replacement, in ion sequestration, and in protection of macromolecules and membranes have been proposed. LEA proteins can act *in vitro* as glassy-state stabilizers, cryoprotectants, and molecular sponges, and can prevent protein aggregation and bind to lipid vesicles or actin filaments.

compared to the sensitive species *setaria*, signifying the relevance of the 21 kDa protein in stress tolerance (Aarati et al., 2003). LEA group 2 proteins include dehydrin, RAB (ABA-responsive), and D11 proteins, which have characteristic lysine-rich regions and are also expressed owing to treatment with ABA (Bray, 1995). LEA group 3 and group 5 proteins are represented by D7 and D29 from cotton, respectively, and contain a repeated tract of 11 amino acids (Bray, 1995). Citrus cell suspensions grown in the presence of 0.2 M NaCl or leaves of citrus plants irrigated with NaCl accumulate a protein (C-LEA5) that has a high similarity with the cotton LEA5 protein (Naot et al., 1995). LEA group 4 protein represents the D113 protein, the synthesis of which is induced in drying cotton seeds, and this protein has a homologue in tomato LE25 (Bray, 1995). In addition to the inducible proteins that have predicted functions, there are many salt-induced proteins that have no specified functions. A protein, RD22, is induced early during seed development in *Arabidopsis* and has homology to an unidentified seed protein from *V. faba* (Bray, 1995). In the roots of salt-stressed barley plants, a “germin”-like protein has been identified (Bray, 1995). Germin is a protein that accumulates during the early growth of wheat plants and has no specified functions.

The most extensively studied proteins from many plant species that accumulate in response to dehydrative conditions like salinity, drought, and low temperature are dehydrins (group 2, LEA), which are hydrophilic Gly-rich proteins (Close, 1997). Although the specific biochemical function of dehydrins has not been demonstrated, they seemingly appear to play a role in protecting membranes from damage (Puhakainen et al., 2004) or act as surfactants that are capable of inhibiting the coagulation of a range of macromolecules and, thereby, preserving structural integrity (Close, 1997). The overexpression of wheat dehydrin *DHN-5* has been shown to enhance tolerance to salinity in *A. thaliana* (Brini et al., 2007).

Transgenic rice plants expressing a LEA protein gene (*HVA1*) from barley showed accumulation of the *HVA1* protein in both roots and leaves, and such plants showed increased tolerance to salinity (Xu et al., 1996). OsLEA3 is a LEA group 3 protein of rice (*O. sativa* L.), the expression of which is induced under salt stress. The accumulation of the OsLEA3 protein in the vegetative tissues of transgenic rice plants enhanced their tolerance to salt stress (Hu, 2008). These observations suggest that LEA proteins play an important role in the protection of plants under salt stress conditions, and that LEA genes hold considerable potential for use as molecular tools for genetic crop improvement toward salinity tolerance (Xu et al., 1996).

The proteomic approach applied to identify differentially expressed proteins in rice panicles in response to salt stress revealed that many proteins were involved in several salt-responsive mechanisms. Such proteins were involved in increasing plant adaptation to salt stress. Some of these proteins had a higher constitutive expression level, and some were associated with up-regulation of antioxidants and up-regulation of proteins involved in translation, transcription, signal transduction, ATP generation, etc. (Dooki et al., 2006). A subcellular proteomics approach was used to identify differentially expressed PM-associated proteins in the salt-tolerant rice variety IR651 in response to salinity. Most of the identified proteins were known to be involved in several important mechanisms of plant adaptation to salt stress, including proteins involved in the regulation of PM pumps and channels, membrane structure, oxidative stress defense, signal transduction, protein folding, the methyl cycle, etc. (Nohzadeh et al., 2007).

### 19.2.1.2 Protein Level in Salt-Stressed Plants

Protein synthesis in plants growing in saline environments is adversely affected. Salt stress results in an overall decrease in protein synthesis with a loss of polyribosomes (Artlip and Funkhouser, 1995). In germinating seeds, as well as during late growth stages of plants, salinity causes impairment in synthesis as well as degradation of proteins. To access the general impact of salt damage on plant growth and metabolism, various investigators have attempted to study the overall status of total proteins and soluble proteins and the pattern of protein synthesis in different parts of plants growing under salinity stress. Salinity in the majority of cases lowers the level of protein in salt-stressed plant parts as a result of the decreased synthesis of protein as well as due to the increased activities of protein-hydrolyzing enzymes. In certain cases, however, an increased protein level is noticed under salinization, possibly due to the increased synthesis of new salt-induced proteins or the decreased activities of proteolytic enzymes.

The process of protein synthesis has shown to be salt sensitive, as observed in wheat germ and *Suaeda maritima* (Greenway and Munns, 1980). Under *in vitro* conditions, a protein-synthesizing system extracted from these species is more sensitive to  $\text{Na}^+$ ,  $\text{K}^+$ , and  $\text{Cl}^-$  than under *in vivo* conditions, as revealed by amino acid incorporation data. A salt-tolerant species like *S. maritima* can maintain optimum growth at a high salt level of 500 mM NaCl, whereas the enzymes extracted from this plant are sensitive to a low level of NaCl (170 mM). This suggests that under *in vivo* conditions, soluble enzymes as well as enzymes of protein-synthesizing mechanisms are comparatively less sensitive to NaCl than isolated enzymes under *in vitro* conditions. Although studying the effects of salt on protein synthesis in *S. maritima*, Hall and Flowers (1973) observed that in this species, protein synthesis is sensitive to salts and that amino acid incorporation decreases under *in vitro* conditions when the KCl concentration in the medium exceeds 50 mM.

In various crop species, a decrease in the protein level in salt-stressed plant parts is attributed to a decrease in protein synthesis, the decreased availability of amino acids, and the denaturation of the enzymes involved in amino acids and protein synthesis (Hall and Flowers, 1973; Popova et al., 1995). In chickpea (*Cicer arietinum* L.), one of the major legume crops for semiarid tropics, a salinity treatment with 100 mM NaCl in a nutrient solution caused a marked decrease in the level of proteins in developing seeds when plants were raised in sand cultures (Murumkar and Chavan, 1986).

When rice (*O. sativa* L.) seeds were germinated under increasing levels of NaCl salinity, a decrease in the total as well as the soluble protein level was observed in the embryoaxes (Dubey and Rani, 1987). A greater decrease in the protein level was observed in the embryoaxes of salt-sensitive cultivars than tolerant cultivars under a similar level of salinization. Dubey and Rani (1987) observed that under 14 dS  $\text{m}^{-1}$  NaCl salinity, the soluble protein level of embryoaxes of salt-sensitive rice cultivars Ratna and Jaya got reduced to almost one-third compared with nonsalinized seeds at 120 h of germination. A moderate salinity level of 7 dS  $\text{m}^{-1}$  NaCl had virtually no effect on the change in the total and soluble protein levels in embryoaxes of germinating seeds of salt-tolerant rice cultivars CSR-1 and CSR-3, whereas a higher salinity level caused a marked decrease in the protein level in the embryoaxes of these cultivars (Dubey and Rani, 1987). In barley plants,

the imposition of NaCl stress leads to a decrease in the leaf protein content and induces marked quantitative and qualitative changes in the polypeptide profiles, affecting mainly the proteins with approximately equal mobility (Popova et al., 1995).

Although salinity causes decreased protein synthesis and increased proteolysis in various plant species, in many cases increased protein levels are observed under salinization in germinating seeds (Dubey and Rani, 1987), growing seedlings (Dubey and Rani, 1989), and different plant parts (Elsamad and Shaddad, 1997). In germinating seeds, endospermic protein hydrolysis is suppressed under salinization. When seeds of rice cultivars differing in salt tolerance are germinated under increasing levels of NaCl salinity, it has been observed that salt treatment suppresses protein depletion from the endosperm of all cultivars, with greater suppression in salt-sensitive cultivars than in salt-tolerant cultivars (Dubey and Rani, 1987).

An apparent increase in the protein level in the endosperms of germinating seeds is observed with an increase in salinity. This can be explained as a result of decreased proteolysis caused by salinity leading to slower depletion of reserve proteins, and not as a result of enhanced protein synthesis (Dubey and Rani, 1987). The NaCl salinity caused a delay in the breakdown of endospermic proteins as well as inhibition in the translocation of hydrolyzed products from endosperms to growing embryoaxes (Dubey, 1983a). The obvious implication is that the inhibition of seedling growth under salinization can also be partly attributed to the delayed mobilization of reserve proteins, because proteolysis is probably the primary, but essential, step toward the synthesis of new proteins for seedlings growth (Ryan, 1973).

When raised under increasing levels of NaCl salinity, rice seedlings show an increased level of total as well as soluble proteins compared with nonstressed seedlings (Dubey and Rani, 1989). During a 5–20 day growth period, when two sets of rice cultivars differing in salt tolerance were examined for the metabolic status of proteins in roots and shoots, it was observed that under a salinity treatment level of  $14 \text{ dS m}^{-1}$  NaCl, the seedlings of tolerant cultivars maintained higher levels of total as well as soluble proteins compared to the seedlings of the sensitive cultivars (Dubey and Rani, 1989). The increased soluble protein level in rice seedlings became more evident when the salinity treatment was raised from a moderate level of  $7 \text{ dS m}^{-1}$  NaCl to a higher level of  $14 \text{ dS m}^{-1}$  NaCl (Dubey and Rani, 1989).

Similar to rice, the NaCl salinity treatment caused an increase in the protein content in cowpea (*Vigna unguiculata* L.) seedlings, pea (*Pisum sativum* L.), Trigonella (*Trigonella foenum-graecum* L. and *T. aphanoneura* Rech. f.), beans (*Phaseolus vulgaris* L.), and *Cajanus cajan* plants as well as in soybean callus cultures (Joshi, 1987; Mehta and Vora, 1987; Vyas and Rao, 1987; Elenany, 1997; Niknam et al., 2006; Dantas et al., 2007). The increased protein level under salinization as noted in these cases appears to be due to the increased synthesis of preexisting as well as certain new sets of proteins (Dubey and Rani, 1989). The increased synthesis of many novel proteins has been noticed in plants subjected to saline stress, but whether such increased synthesis is responsible for a net increase in the total and soluble protein levels of stressed plants remains to be investigated.

To understand the mechanism of salt tolerance in crops, various investigators have studied the metabolic status of proteins and amino acids in germinating seeds and seedlings using cultivars differing in salt tolerance (Dubey and Rani, 1987, 1989; Elsamad and Shaddad, 1997; Moons et al., 1997; Ahmed et al., 2001; Dantas et al., 2007). Especially in rice (*O. sativa* L.), a staple food crop for the majority of the world population, salt-tolerant cultivars are characterized by a higher value of protease-specific activity as well as a higher total and soluble protein content in germinating seed parts under control and salt treatments, when compared with sensitive seedlings (Dubey and Rani, 1989). This shows the salt-tolerance ability to be associated with a possible higher protein level in rice, seemingly endogenous proteins that are either not found or are very poorly expressed in sensitive cultivars.

Using a salt-tolerant rice variety, Pokkali, and a salt-sensitive variety, Taichung N1, a cDNA clone *oslea3*, encoding a LEA group 3 protein, was identified that accumulated to higher levels in the salt-tolerant variety compared with the sensitive one on imposition of salt stress (Moons et al., 1997). Further, this stress-induced protein and its mRNA declined less rapidly on sustained salt

shock in tolerant cultivars than the sensitive ones. Such observations indicate that the differential regulation of protein expression is associated with varietal differences in salt stress tolerance (Moons et al., 1997).

Soybean (*Glycine max*) cultivars differing in salt tolerance show different levels of proteins and amino acids when grown in the presence of NaCl (Elsamad and Shaddad, 1997). Salt-tolerant soybean cultivars, Clark and Forest, accumulate higher levels of soluble proteins, whereas the sensitive cultivar Kint shows a decrease in the soluble protein level when grown in saline soils (Elsamad and Shaddad, 1997). These observations indicate that in rice and soybean plants, the salt-tolerance ability is associated with a higher level of proteins, which are seemingly endogenous proteins that are either not found or are very poorly expressed in sensitive cultivars on imposition of salinity.

### 19.2.1.3 Enzyme Levels in Salt-Stressed Plants

Salinity induces changes in the activities of proteolytic (Dubey, 1983a; Dubey and Rani, 1987, 1990), amylolytic (Dubey, 1983a,b; Dreier et al., 1995), nucleolytic (Dubey, 1985), phosphorolytic (Dubey et al., 1987; Dubey and Sharma, 1989, 1990; Banuls et al., 1995; Lin et al., 1997), oxidative (Mittal and Dubey, 1995), antioxidative (Piqueras et al., 1996; Azevedo-Neto et al., 2006; Khosravinejad et al., 2008; Shafi et al., 2009), photosynthetic (Popova et al., 1995), and nitrogen assimilatory enzymes (Dubey, 1997; Debouba et al., 2007), in germinating seeds and in growing plants. Salinity causes either an increase or a decrease in the activity of enzymes, depending on the nature of the enzymes, the extent of stress, the plant parts studied, and the genotypes of plant species differing in salt tolerance.

In the endosperms of germinating rice seeds, salinity causes a decrease in the activities of hydrolytic enzymes  $\alpha$ -amylase, protease, ribonuclease, phosphatase, and phytase (Dubey, 1983a,b; Dubey, 1985; Dubey and Rani, 1987). The decrease is more in salt-sensitive than in salt-tolerant varieties. In growing seedlings of rice, salinity enhances the activities of nucleases (Dubey, 1985), proteases (Dubey, 1985; Dubey and Rani, 1990), peptidases (Dubey and Rani, 1990), phosphatases (Dubey et al., 1987; Dubey and Sharma, 1989, 1990), and oxidases (Mittal and Dubey, 1991). Genotypes of rice species differing in salt tolerance maintain different levels of salinity-induced activities of enzymes.

Barley plants grown in the presence of 200 mM NaCl show stimulation in  $\beta$ -amylase activity in leaves (Dreier et al., 1995).  $\beta$ -Amylases are regarded as stress-induced proteins in barley (Dreier et al., 1995). The NaCl treatment resulted in a decrease in the activities of  $\alpha$ -amylase,  $\beta$ -amylase, and  $\alpha$ -glucosidase enzymes involved in the seed germination process of two lentil cultivars, Castelluccio and Eston. In contrast, seeds of two bean cultivars, Pantelleria and Ustica, showed higher enzyme activities involved in the germination process, in response to salt stress (Sidari et al., 2008). Certain enzymes involved in the synthesis of osmolytes show a marked increase under salinity stress (Ramagopal, 1993). The enzymes of proline biosynthesis,  $\Delta^1$ -pyrroline-5-carboxylate synthetase (P5CS), and  $\Delta^1$ -pyrroline-5-carboxylate reductase; the penultimate enzyme of betaine biosynthesis, betaine aldehyde dehydrogenase, and the enzyme of sorbitol biosynthesis; aldose reductase, show increased activity in many plants subjected to salt stress (Ramagopal, 1993; Igarashi et al., 1997). Genes that code for key enzymes involved in osmolyte biosynthesis have been isolated from barley, spinach, sugar beet, soybean, and rice plants (Ramagopal, 1993). The salinity treatment of 7 and 14 dS m<sup>-1</sup> NaCl led to a significant increase in the levels of free amino acids with a substantial elevated level of proline in rice seedlings (Dubey and Rani, 1989). P5CS is the rate-limiting enzyme in proline biosynthesis in plants. It was observed that salt stress increased the P5CS activity, thus increasing the proline content in the roots of cucumber seedlings (Duan et al., 2006). Salt-tolerant varieties of rice show a higher level of expression of the enzyme P5CS and its mRNA compared with salt-sensitive varieties grown in the saline medium (Igarashi et al., 1997). Transgenic tobacco (*N. tabacum*) plants overexpressing the *p5cs* gene that encodes P5CS produced 10- to 18-fold more proline and exhibited better performance under salt stress (Kishor et al., 1995). Tobacco plants expressing *Arabidopsis* P5CS also showed higher levels of proline and enhanced resistance to the applied salt (Yamchi et al., 2007). The enzymes involved in membrane transport, such as PM-ATPase in cotton seedlings (Lin et al., 1997) and Ca<sup>2+</sup>-ATPase in tomato plants (Ramagopal, 1993), show a higher level of

activity under salinization. An increased turnover of the tonoplast  $H^+$ -ATPase was observed in the leaves of *C. sinensis* plants under salinity stress (Banuls et al., 1995).

The activities of the oxidative enzymes polyphenol oxidase and indole-3-acetic acid oxidase increase in the seedlings of salt-tolerant as well as salt-sensitive rice cultivars under salinization, and the extent of the increase differs in the two sets of cultivars (Mittal and Dubey, 1995). Similarly, phosphohydrolases show varying behavior under salinity in rice plants of differing salt tolerance.

The changes in the activity behavior of the enzymes acid phosphatase, alkaline phosphatase, and ATPase isolated from the chloroplasts of two sets of rice seedlings differing in salt tolerance when grown under increasing levels of NaCl salinity are shown in Table 19.2. As it is evident from the table, the acid phosphatase activity was more inhibited owing to salinity in salt-sensitive cultivars compared with the salt-tolerant ones, whereas the activity of alkaline phosphatase increased in the salt-sensitive seedlings but not in the salt-tolerant ones. Further, salinity caused an enhancement of the ATPase activity in both sets of rice seedlings, with a greater enhancement in tolerant cultivars than in the sensitive ones. The activities of the antioxidant enzymes superoxide dismutase (SOD), peroxidase, and glutathione reductase (GR) increase in callus cultures of *Citrus limon* (Piqueras et al., 1996), *O. sativa* (Elenany, 1997), and *Medicago sativa* (Safarnejad et al., 1996) grown in the presence of NaCl. In soybean callus cultures, an increase in the GR activity in response to NaCl constitutes an adaptive response of callus tissues to NaCl (Elenany, 1997).

The level and activity of the key enzyme of photosynthesis in  $C_3$  plants, ribulose-1,5-bisphosphate carboxylase, decrease in barley plants on the imposition of NaCl stress (Popova et al., 1995). The prime enzyme of nitrate assimilation, nitrate reductase (NR), has been extensively studied for its behavior in different plant species under salinization (Dubey and Pessarakli, 1995; Dubey, 1997; Debouba et al., 2007). Salinity effects on NR activity are varied and depend on the type and extent of salinity as well as on the genotypes of the plants studied. In intact tissues of wheat, lentil (*Lens esculenta* Moench), mulberry (*Morus abla*), sorghum, and tobacco plants, the NR activity decreases owing

*Notes:* T and S in parentheses indicate tolerant and sensitive rice cultivars, respectively. Enzyme units are expressed as  $\mu\text{mol}$  substrate hydrolyzed  $\text{h}^{-1} \text{mg}^{-1}$  protein.

to NaCl salinity (Dubey, 1997), whereas, in rice plants, the behavior of NR varies in genotypes differing in salt tolerance when raised under NaCl salinity (Katiyar and Dubey, 1992). The salt-sensitive rice cultivars Ratna and Jaya show a decrease in the shoot and root, whereas the salt-tolerant cultivars CSR-1 and CSR-3 show increased activity of the enzymes in both of these tissues under salinization (Katiyar and Dubey, 1992).

Isoenzyme profiles of many enzymes are influenced by salinity. In certain cases, some of the molecular forms of enzymes present in nonsalinized plants disappear in stressed plants, whereas, in other cases, certain new molecular forms of enzymes appear under salinization. In shoots of 15-day-old nonsalinized rice seedlings, four acid phosphatase isozymes were observed, whereas when seedlings were raised at a salinity level of 14 dS m<sup>-1</sup> NaCl, only one isoenzyme remained detectable (Dubey and Sharma, 1989). The decreased number of acid phosphatase isoenzymes at a higher level of salinization paralleled the decreased activity of the enzyme under such conditions (Dubey and Sharma, 1989).

In the young embryoaxes of germinating seeds, certain new molecular forms of acid phosphatases appear under salinization. When acid phosphatase isoforms from the embryoaxes of germinating seeds of the salt-sensitive rice cultivar Jaya and the salt-tolerant cultivar CSR-1 were compared at 48 and 96 h of germination under increasing levels of NaCl salinity, it was observed that certain new isoenzyme forms appeared in both sets of cultivars under salinization (Dubey and Sharma, 1990). Further, a great number of isoenzymes were observed in the embryoaxes of salt-tolerant rice varieties than in those of salt-sensitive varieties under both controls as well as salt treatments (Dubey and Sharma, 1990). Therefore, under salinization, certain isoforms of acid phosphatase are not synthesized, whereas the synthesis of certain new isoforms is induced depending on the plant parts and the genotypes studies. It has been shown that salt tolerance is associated with the presence of a large number of acid phosphatase isoenzymes (Dubey and Sharma, 1990).

The specific activities and patterns of peroxidase and SOD isoenzymes are altered significantly in plants subjected to salinity stress. Rice seedlings differing in salt tolerance possess constitutively different number of peroxidase isoforms in nonsalinized seedlings. When these seedlings were raised under NaCl salinity, certain new isoforms of peroxidases appeared, and the intensities of some of the preexisting isoenzymes increased. In 15-day-old seedlings of a salt-tolerant rice cv. CSR-1, three isoenzymes were observed in roots and five in shoots, whereas in a salt-sensitive cv. Ratna, six isoenzymes were observed in the roots as well as in the shoots (Mittal and Dubey, 1991). Salt-tolerant embryonic callus cultures of lemon (*C. limon* L. Burn) exhibited an increase in the activity of antioxidant enzymes involved in oxygen metabolism with an increase of peroxidase activity and with the induction of a new SOD isozyme (Piqueras et al., 1996). These studies and other similar studies suggest that peroxidase and SOD isoenzymes can serve as useful markers in the analysis of gene functions and metabolic regulations, including salt-tolerance characteristics (Mittal and Dubey, 1991).

Like acid phosphatase and peroxidases, isoenzyme profiles of ribonucleases (Mittal and Dubey, 1990) and  $\alpha$ -amylases (Dubey, 1983b) are also influenced under salinization. The presence of different isoenzyme patterns of phosphatases, peroxidases, SOD, and ribonucleases in salt-sensitive and salt-tolerant genotypes of crops strengthens the view that salt tolerance or sensitivity depends on the genetic and biochemical makeup of the species. Also, specific molecular forms of the isoenzymic proteins, which appear to be constitutive proteins, are possibly associated with the salt-tolerance or sensitivity characteristics. However, the mechanisms of the expression of intrinsic isoenzyme proteins related with sensitivity or tolerance and of those isoenzymic proteins that specifically appear under salinization remain to be investigated.

### 19.2.2 DROUGHT

Water is the earth's most distinctive constituent and is an essential ingredient of all life. Its deficit is one of the most common environmental factors limiting crop productivity. Drought is a natural calamity and has devastating effects on crop yields. Crop plants are frequently subjected to drought

during the course of their lifetimes. However, certain stages, such as germination, seedling, and flowering, are the most critical for water deficit damage. Stress imposed during these stages drastically affects crop yields. Drought reduces plant growth and manifests several morphological and biochemical alterations in plants, ultimately leading to a massive loss in yield. A reduction in the efficiency of key processes including protein synthesis, photosynthesis, respiration, and nucleic acid synthesis is among the biochemical manifestations of drought. Drought inhibits protein synthesis, induces the synthesis of small sets of stress-specific proteins, promotes important modification in gene expression, causes activation or inhibition in the activities of many enzymes, and leads to changes in the ultrastructures of tissues. A considerable amount of work has been done by various groups of investigators in the last few years to understand the mode of protein synthesis in plant parts under drought conditions (Bewley and Larsen, 1982; Dasgupta and Bewley, 1984; Heikkilä et al., 1984; Baker et al., 1995; Zhang et al., 1996; Close, 1997; Pelah et al., 1997; Bibi et al., 2009; Ke et al., 2009), the level of proteins in stressed plants (Rai et al., 1983; Kumar and Singh, 1991), and the activities of key enzymes influenced under drought (Lodh et al., 1977; Mali et al., 1980; Geigenberger et al., 1997; Igarashi et al., 1997; Sharma and Dubey, 2004, 2005a,b).

#### 19.2.2.1 Drought-Induced Protein Synthesis

Drought causes alteration in the gene expression in plants, leading to an inhibition of protein synthesis as well as an enhanced synthesis of certain stress-specific proteins. Quantitative and qualitative changes occur in the synthesis of proteins in plants in response to water deficit. It is well documented that in various crops, drought causes a tissue- and organ-specific differential genomic expression, which results in changes in the patterns of protein synthesis in cells (Bewley and Larsen, 1982; Dasgupta and Bewley, 1984; Heikkilä et al., 1984; Yoshimura et al., 2008; Ke et al., 2009; Si et al., 2009). Plants growing in drought condition or cells undergoing adaptation to drought show both a decrease as well as an increase in small sets of cellular proteins. Many of these proteins that are specifically synthesized under drought have been isolated and well characterized (Singh et al., 1987; Claes et al., 1990; Close, 1997; Pelah et al., 1997). Evidence is increasing in favor of a relationship between the accumulation of drought-induced proteins and physiological adaptations to water limitation (Riccardi et al., 1998).

A mild to moderate drought condition decreases the efficiency of protein synthesis in plants, but such plants recover and their protein synthesis returns to normal when water stress is reversed or plants are rewatered (Bewley and Larsen, 1982). The imposition of drought alters the status of the protein-synthesizing complex polyribosomes in the tissues. The content of polyribosomes decreases with one set of drought stress, and the extent of such a decrease varies among different plant species and even in different organs of the same plant (Scott et al., 1979; Bewley and Larsen, 1982). Studies in maize (Bewley and Larsen, 1982) and wheat (Scott et al., 1979) have indicated that increasing the level of drought causes a decrease in the polyribosome level. Plant species that can survive under drought stress show a greater capacity to produce polyribosomes in the tissues.

Various investigators have demonstrated the synthesis of drought-specific proteins in different crops (Dasgupta and Bewley, 1984; Heikkilä et al., 1984; Singh et al., 1987; Claes et al., 1990; Baker et al., 1995; Zhang et al., 1996; Close, 1997; Pelah et al., 1997). Many of these proteins also appear in response to the application of ABA, suggesting that ABA is a signal in the stress response. Genes encoding these proteins have been isolated and studied using DNA probes. Like salinity stress, drought-inducible proteins have been grouped in several families depending on the DNA sequences of genes, their expression characteristics, and their predicted functions.

The induced synthesis of novel proteins, including enzymes involved in the biosynthesis of osmoprotectants, HSPs, LEA proteins, chaperones, enzymes associated with detoxification, transcription factors, kinases, and phosphatases, in response to drought has been reported in several plant species (Jiang and Huang, 2002; Khurana et al., 2008; Ke et al., 2009). Major families of drought-induced proteins have been described as LEAs, RABs, dehydrins, and vegetative storage proteins (Artlip and Funkhouser, 1995). LEA proteins have been further subdivided into several groups: group 1

(D19 protein from cotton), group 2 (D11 from cotton), group 3 (D7 from cotton), and group 5 (D29 from cotton). Many of these proteins are hydrophilic and are soluble on boiling, and are therefore expected to be located in the cytosol. The precise function of LEAs is still unknown, but substantial evidence indicates their involvement in desiccation tolerance (Khurana et al., 2008). It is predicted that most of these proteins are involved in protecting cellular structures and components from dehydration associated with water deficit.

Among proteins in plants that accumulate in response to dehydrative forces or drought, dehydrins have been the most commonly observed. Rice, barley, maize, pea, and *Arabidopsis* plants show an increased synthesis of dehydrins under osmotic stress (Ramagopal, 1993). Dehydrins are composed of several typical domains joined together in a few characteristic patterns with numerous minor permutations. Dehydrin polypeptides are made up of less than 100 to nearly 600 amino acid residues (Close, 1997). Although the fundamental biochemical mode of action of dehydrins has not been demonstrated, it is believed that dehydrins are surfactants and, thereby, they inhibit the coagulation of a range of macromolecules and preserve the structural integrity of the cell (Close, 1997). Genes encoding dehydrins are also ABA regulated. In dehydrated leaves of tomato, maize, and *Arabidopsis* plants, endogenous ABA levels increase with the simultaneous increase in the levels of dehydrins and their mRNAs (Bray, 1995). Dehydrins are localized primarily in the cytoplasm of root and shoot cells (Bray, 1995).

In certain plant species, the synthesis of dehydrin-like proteins has been observed under osmotic stress or under treatment with ABA. In *Stellaria longipes*, the synthesis of a dehydrin-like protein is induced as a result of treatment with ABA or under osmotic stress (Zhang et al., 1996). A sequence analysis of this protein indicates that it shares some similarity in structural features with dehydrins of other plants and also exhibits certain unique characteristics (Zhang et al., 1996). In castor bean, the synthesis of dehydrin-like proteins is tissue specific and is dependent on the physiological stage of the seed. Patterns of water-deficit-induced dehydrin-related polypeptides in endosperms differ from those induced during late seed development (Han and Kermode, 1996). In drought-stressed roots and shoots of *Lathyrus sativus*, dehydrin-like transcripts accumulate, which are also expressed in unstressed seedlings owing to the ABA treatment (Sinha et al., 1996). A novel protein with 40 kDa molecular weight has been detected in pea plants under desiccation. The deduced amino acid sequence of this protein indicates two lysine-rich blocks; however, the remainder of the sequence differs markedly from other pea dehydrins (Robertson and Chandler, 1994). By analogy with heat-shock cognate proteins, this protein has been designated as a dehydrin cognate (Robertson and Chandler, 1994). Transgenic *Arabidopsis* plants overexpressing the wheat dehydrin *DHN-5* were shown to be more tolerant to water deprivation as compared to wild-type plants (Brini et al., 2007). It was proposed that Dhn-5 contributes to an improved tolerance to drought stress through osmotic adjustment (Brini et al., 2007).

Like dehydrins, the RAB and D11 (group 2) family of proteins are also ABA regulated and possess a characteristic lysine-rich region with consensus amino acid sequences repeated at least two times. Proteins of this family have been identified in many plant species, including maize, tomato, wheat, alfalfa, *Arabidopsis*, rice, and castor (Mundy and Chua, 1988; Ramagopal, 1993; Bray, 1995; Han and Kermode, 1996). LEA group 1 (D19) proteins, which are devoid of cysteine and tryptophane, have been detected in cotton, barley, and carrot under water deficit (Ramagopal, 1993). It is suggested that LEA group 1 proteins function in a water-binding capacity creating a protective aqueous environment (Bray, 1995). LEA group 3 and LEA group 5 proteins, which are represented by D7 and D29 proteins, respectively, from cotton contain a repeated tract of 11 amino acids. These proteins have been isolated from desiccating mature cotton embryos, chloroplasts of *Craterostigma plantagineum*, and citrus seedlings exposed to drought (Bray, 1995; Naot et al., 1995). A citrus cell suspension in response to salt stress, leaves of citrus plants irrigated with NaCl, or seedling exposed to drought led to an osmotic stress-induced elevated level of LEA5 proteins and their mRNAs (Naot et al., 1995). Another group of proteins, group 4, is represented by the D113 protein, which has a homologue in tomato and is expressed in drying cotton seeds (Ramagopal, 1993; Bray, 1995).

Using a transgenic approach, it is suggested that LEA proteins play an important role in the protection of plants under drought stress. The expression of the barley (*Hordeum vulgare* L.) LEA protein gene, *HVA1*, in rice cell suspension leads to a higher level of accumulation of this protein, and such plants show an increased tolerance to water deficit (Xu et al., 1996). LEA group 4 genes from the resurrection plant *Boea hygrometrica* were shown to confer dehydration tolerance in transgenic tobacco (Liu et al., 2009). These proteins are likely to play a role in the general protection of the plant cells during dehydration and affect membrane and protein stability. LEA4-1 cDNA cloned from *Brassica napus* was overexpressed in transgenic *Arabidopsis* plants. The transgenic *Arabidopsis* plants expressing the *BnLEA4-1* gene under either the constitutive CaMV35S or the abiotic stress-inducible RD29A promoter showed an enhanced tolerance to drought (Dalal et al., 2009).

Osmotin, the 26 kDa protein, which is synthesized and accumulates in cells undergoing osmotic adjustment to NaCl, also accumulates in cells undergoing osmotic adjustment to PEG (Singh et al., 1987). ABA, which is known to induce osmotic adjustment in cells, also induces the synthesis of osmotin. Osmotin synthesis is regulated by ABA, but its accumulation is dependent on the extent of drought stress and the adjustability of the cells to stress. Like dehydrins, osmotin also is the much extensively studied protein that accumulates under water and salinity stresses in several plant species like tobacco, triplex, tomato, and maize (Ramagopal, 1993). An osmotically regulated glycine- and threonine-rich protein was identified in rice by Mundy and Chua (1988). This protein is a product of a small ABA-responsive gene, *rab 21*. Osmotic stress imposed by PEG or dessication leads to an increase in the level of ABA, and, in turn, the *rab 21* gene is induced and expressed to synthesize these proteins in rice tissues. The constitutive expression of an osmotin gene in transgenic tobacco was shown to improve its tolerance to drought stress (Barthakur et al., 2001). Parkhi and coworkers (2009) provided a direct evidence for a protective role of osmotin in cotton plants experiencing drought stress by transforming cotton plants with apoplastically secreted tobacco osmotin. Under PEG-mediated drought stress, the osmotin-expressing seedlings showed better growth performance, and higher relative water content and proline levels, while showing reduced H<sub>2</sub>O<sub>2</sub> levels, lipid peroxidation, and electrolyte leakage.

From rice cv. Tainchung native 1, a 15 kDa protein that accumulates in the sheaths and roots of mature plants and seedlings when subjected to either osmotic stress or after treatment with ABA has been isolated and characterized (Claes et al., 1990). Rice varieties show considerable differences in sensitivity to drought; however, in many of the varieties examined, water deficit created as a result of PEG led the induced synthesis of one 26 kDa protein with a pI of 6 (Perezmolphebaltch et al., 1996). In certain varieties of rice, drought causes the accumulation of 18 and 85 kDa proteins, called stress-associated proteins, that also accumulate under salinity and high and low temperatures (Pareek et al., 1997).

A boiling-stable protein (BspA) has been shown to accumulate in the roots of *Populus popularis* plants under drought (Pelah et al., 1997). In addition to BspA, plants also show accumulation of the drought stress-related proteins dehydrin (dsp-16) and sucrose synthase (SS) under water deficit (Pelah et al., 1997). In a highly drought-tolerant legume, cowpea (*Vigna unguiculata*), which shows an about 160 times higher accumulation of ABA in drought-stressed conditions compared with unstressed plants, two cDNA clones were identified in drought-stressed plants, CPRD 8 and CPRD 22, which encode putative proteins that are related to old yellow enzyme and LEA group 2 proteins, respectively (Iuchi et al., 1996b). However, in cowpea plants dehydrated for 10h, two additional cDNA clones, CPRD 12 and CPRD 46, were identified, which encode putative proteins related to nonmetallo-short-chain alcohol dehydrogenase (ADH) (CPRD 12) and chloroplastic lipoxxygenase (CPRD 46). These genes are also induced under salinity stress (Iuchi et al., 1996a).

Exposure of *A. thaliana* to drought stress results in the accumulation of the RAB 18 protein, and such plants develop an enhanced freezing tolerance (Mantyla et al., 1995). A progressive water deficit in whole *Solanum tuberosum* plants leads to an about 2.5-fold increase in the leaf ABA content and the synthesis of two chloroplastic proteins of 32 and 34 kDa, namely, CDSP 32 and CDSP 34, which

are synthesized in the stroma and in the thylakoids, respectively (Pruvot et al., 1996). A 65 kDa protein with a *pI* value of 5.2 has been shown to accumulate gradually in tomato leaves during drought stress (Tabaeizadeh et al., 1995). The quantification of this protein by gold labeling indicates that the synthesis of this protein occurs in nuclei and chloroplasts as well as in some cytoplasmic regions of the cells in drought-stressed plants (Tabaeizadeh et al., 1995).

Certain additional families of proteins and their genes that are induced by water deficit have been identified in specific plant species. In *Arabidopsis*, 77.9 and 64.5 kDa hydrophilic proteins accumulate under drought stress, and their genes, which are adjacent to each other in the genome, have been characterized from different laboratories (Bray, 1995). The synthesis of these proteins also occurs with the application of ABA. Similarly, a family of genes and their products, glycine-rich proteins, which are hydrophilic and ABA responsive, have been identified in alfalfa plants under drought stress (Bray, 1995). However, no specific predictions about the functions of these *Arabidopsis* and alfalfa proteins have been made under stressful conditions.

A gene named *ATHB-7*, which belongs to a class of recently discovered homeobox genes found as yet only in plants, has been characterized in all organs of *A. thaliana*. The expression of this gene and the synthesis of its proteins, called homodomain-leucine zipper (HD-Zip) proteins, are induced severalfold under water deficit as well as by an exogenous treatment with ABA (Soderman et al., 1996). It is suggested that *ATHB-7* is transcriptionally regulated in an ABA-dependent manner and may act in a signal transduction pathway mediating a drought response (Soderman et al., 1996). Besides, cytosolic and organellar proteins, which are induced under drought stress, in the cell walls of bean (*P. vulgaris*) seedlings, two proteins, of 36 and 33 kDa, have been identified that are glycosylated and accumulate when plants are subjected to a gradual loss of water (Covarrubias et al., 1995).

HSPs are known to accumulate in plants under drought stress (Arora et al., 1998; Jiang and Huang, 2002). One of the presumed functions of HSPs is related to the prevention of protein denaturation during cellular dehydration. The overexpression of *AtHsp90.2*, *AtHsp90.5*, and *AtHsp90.7* in *A. thaliana* enhanced plant sensitivity to drought stress (Song et al., 2009). When a rice small HSP gene, *sHSP17.7*, was overexpressed in the rice cultivar Hoshinoyume, an enhanced tolerance to drought stress was observed in transgenic lines (Sato and Yokoya, 2008). At the end of drought treatments, only transgenic seedlings with higher expression levels of the *sHSP17.7* protein were found to regrow after rewatering. Transgenic tobacco plants constitutively expressing elevated levels of NtHSP70–1 showed an enhanced tolerance to drought stress (Cho and Choi, 2009).

Studies conducted by various investigators related to the effects of drought stress on the protein synthesis in many important crops suggest that drought stress severely affects protein synthesis, alters gene expression and protein profiles in stressed tissues, and induces the synthesis of specific-stress-induced proteins. Many of these proteins are hydrophilic and belong to specified families and have predicted functions in protecting the cells from drought stress. Some of the stress-induced proteins appear to be tissue specific, whereas others do not appear to be specific for any particular tissue or organ. Genetic expression studies reveal that among the stress-induced proteins that are well characterized, the majority are the product of ABA-responsive genes. How stress conditions signal an increased production of ABA, how ABA modulates the expression of these genes, and what is the functional role of stress-responsive proteins in dehydration tolerance, such as osmoprotectants, radical scavengers, protectants of subcellular organelles and macromolecules, or as regulatory proteins, remain yet to be investigated in detail. An immunoblot analysis performed in the leaves of drought-tolerant (Katya and Zlatitza) and drought-sensitive (Sadovo and Miziya) wheat varieties for the detection of ribulose-1,5-bisphosphate carboxylase/oxygenase (RUBISCO), RUBISCO activase (RA), RUBISCO binding protein (RBP), dehydrins, and some HSPs and ATP-dependent calpain protease (Clp) proteins under drought stress revealed that the drought-tolerant varieties Katya and Zlatitza had higher levels of these proteins, especially RBP and Clp proteases, compared to the sensitive varieties (Demirevska et al., 2008).

### 19.2.2.2 Protein Level in Drought-Stressed Plants

The levels of total as well as soluble proteins get altered in plants growing under drought conditions compared with plants growing under nonstressed conditions. Various workers have observed either a decrease (Barnett and Naylor, 1966; Hsiao, 1973; Kumar and Singh, 1991; Gogorcena et al., 1995; Yu et al., 1996; Boo and Jung, 1999; Sharma and Dubey, 2005a; Bai et al., 2006) or an increase (Rai et al., 1983; Kumar and Singh, 1991) in the levels of total or soluble proteins in different organs of plants subjected to drought stress. The increased or decreased levels of proteins depend on the plant species and organ studied as well as the severity of the stress.

Sharma and Dubey (2005a) observed a concomitant decrease in the content of the total soluble protein with an increasing level of water deficit in roots as well as in shoots of growing rice seedlings. Shah and Loomis (1965) observed decreased contents of soluble and total proteins in sugar beet leaves from data recorded on a per gram of dry weight basis when the plants were subjected to progressive drought stress. These investigators observed that the response to drought was quick and could be reversed by rewatering the plants. This indicates that the effects of drought are reversible to a certain extent. According to Hsiao (1973), the rapid response of plants under drought stress and its quick reversibility by rewatering suggest that drought affects protein synthesis mainly at the translation level. When Bermuda grass plants were subjected to increasing levels of drought, a decrease in the soluble protein level was observed (Barnett and Naylor, 1966). In whole chloroplasts as well as in chloroplast membrane fractions isolated from drought-resistant as well as drought-sensitive genotypes of drought-stressed wheat plants, a decrease in the protein content was observed compared with nonstressed plants (Kulshrestha et al., 1987). Mung bean seedlings differing in drought stress tolerance, when raised under increasing water deficits, showed a decrease in the protein level in the axis (Kumar and Singh, 1991).

When seedlings of chickpea were used to investigate drought stress-induced variations in protein profiles of germinating cotyledons using the SDS-PAGE analysis, a quantitative decrease in the level of some high-molecular-weight proteins was observed on the fifth day of germination and some new germination-related proteins appeared on the seventh day in control. In cv. CM-2000, a delayed expression of two proteins with mol. wt. 100 and 60.8 kDa, respectively, was observed under drought stress, while these proteins were expressed earlier in cv. CM-94/99 (Bibi et al., 2009). In *Lycopersicon chilense* whole plants as well as in cell suspensions, drought stress leads to a decreased synthesis of a proline-rich 12.6 kDa protein in the cell walls (Yu et al., 1996). This is possibly attributed to the downregulation of its gene, designated PTGRP under desiccation. In the nodules of drought-stressed (−2.03 MPa) pea (*P. sativum* L. cv. Frilene) plants, an about 30% decline in the soluble protein level was observed compared with well-watered plants (Gogorcena et al., 1995). When rice varieties differing in drought stress tolerance were examined for changes in the protein profiles in different organs due to drought stress, it was observed that in the two cultivars, Sinaloa and IR 10120, the synthesis of several polypeptides decreased owing to PEG-induced drought (Perezmolphebalch et al., 1996). It is suggested that in rice, the extent of the decrease in the levels of proteins or changes in protein profiles in different organs due to water deficit are cultivar specific (Perezmolphebalch et al., 1996).

A decreased level of the total as well as of the soluble proteins in drought-stressed tissues (Kumar and Singh, 1991) appears to be due to more degradation of proteins as well as due to the overall inhibition in protein synthesis under drought. It has been observed that drought-stressed plant parts show a high protease activity compared with nonstressed plants (Thakur and Thakur, 1987). The high activity of protease in drought-stressed plants appears to be of adaptive significance, because it leads to the accumulation of free amino acids as a result of the degradation of proteins. Increased levels of free amino acids together with organic acids and quaternary ammonium compounds serve as compatible cytoplasmic solutes to maintain the osmotic balance between the cytoplasm and the vacuole under conditions of drought stress (Barnett and Naylor, 1966).

Genotypes of crop cultivars differing in drought tolerance, when raised under increasing levels of drought, show different levels of proteins as well as specific activities of protease. Seedlings of drought-tolerant mung bean genotypes show a higher protein content in embryoaxes as well as in cotyledons compared with drought-sensitive genotypes when raised at a  $-10.0$  bar moisture stress level (Kumar and Singh, 1991). Similarly, drought-resistant maize (*Zea mays* L.) cultivars show a high protease activity at higher levels of drought stress, whereas an inhibition in protease activity is noticed under higher drought stress levels in sensitive cultivars (Thakur and Thakur, 1987). While comparing the total protein and free amino acid pool size in drought-resistant and drought-sensitive cultivars of *C. arietinum* and *Z. mays*, Rai et al. (1983) observed that resistant plants are characterized by an increase over nonstressed plants in total protein and free amino acid levels.

Certain investigators have observed an increase in protein levels in plants subjected to drought stress (Rai et al., 1983; Kumar and Singh, 1991). Genotypes of *C. arietinum* cultivars, differing in drought stress tolerance, when raised under increasing osmotic potential levels, show increased protein levels in shoots compared with nonstressed plants (Rai et al., 1983). A drought-resistant *C. arietinum* cv. C-214 showed an increase of 60% protein over control at an osmotic potential of  $-3$  atm, whereas a sensitive cultivar, G-130, showed a 15% increase over control under similar conditions of stress (Rai et al., 1983). Similarly, when drought-resistant *Z. mays* cv. Ageti-76 plants were grown under increasing osmotic potentials in the range of 1–10 atm, an increase in the protein content was noticed, reaching 190% of control (Rai et al., 1983). Similarly, in the cotyledons of germinating mung beans under drought stress, an increased protein level was noticed when compared with nonstressed germinating seeds (Kumar and Singh, 1991). These observations indicate that drought has varying effects on the level of proteins in different crop species, and the stress-induced response depends on the species of the crop examined, and it may vary even in different organs within the same species.

### 19.2.2.3 Enzyme Levels in Drought-Stressed Plants

The normal metabolism of plants growing under drought conditions is adversely affected with a concomitant disturbance of the enzymatic constitution of the plants. Drought stress lowers the levels of many enzymes in the tissues (Mali et al., 1980; Thakur and Thakur, 1987; Gogorcena et al., 1995; Du et al., 1996; Reddy, 1996; Geigenberger et al., 1997; Sharma and Dubey, 2005b; Xu and Zhou, 2005). The activities of certain enzymes increase as a result of drought stress (Hsiao, 1973; Lodh et al., 1977; Thakur and Thakur, 1987; Bray, 1995; Igarashi et al., 1997; Sharma and Dubey, 2005a). Nitrogen assimilation and photosynthetic efficiency are reduced in drought-stressed plants mainly owing to the decreased activities of the key enzymes involved in these processes. NR, the prime enzyme in the N assimilation process, is markedly inhibited by drought (Hsiao, 1973; Xu and Zhou, 2005). The effect of mild ( $-0.5$  MPa) as well as moderate ( $-2$  MPa) levels of drought imposed for 24 h, on the level of protein, and the activities of enzymes NR, glutamine synthetase (GS), alanine aminotransferase (AlaAT), and aspartate aminotransferase (AspAT) in the roots and shoots of 20-day-grown rice plants are shown in Table 19.3. As it is evident from the table, drought stress causes a drastic decline in the protein levels as well as in the activities of the enzymes of  $\text{NO}_3^-$  assimilation, NR and GS, whereas the key enzymes of amino acid metabolism, AlaAT and AspAT, show increased activity under a mild level of drought; however, under a moderate drought stress of  $-2$  MPa, a pronounced inhibition in the enzyme activity is noticed. The activity of NR is directly associated with protein synthesis and plant growth, and both of these processes are adversely affected under drought (Sinha and Nicholas, 1981). Rice seedlings subjected to severe drought stress showed a marked decline in the levels of both NRact (NR activity in the presence of  $\text{Mg}^{2+}$  representing the non-phosphorylated NR state) and NRmax (NR activity in the presence of EDTA representing maximum NR activity), whereas the NR activation state remained almost unaltered (Sharma and Dubey, 2005b).

**TABLE 19.3**  
**Drought Stress–Induced Decrease in the Level of Protein and Alteration in the Activity of Enzymes of N Metabolism in Roots (R) and Shoots (S) of 20-Day-Grown Rice Plants. Two Rice Cultivars were Used for the Study**

| Rice Cultivars | Drought Stress |     | Protein (mg g <sup>-1</sup> fw) | Nitrate Reductase                                                 | Glutamine Synthetase                                                     | Alanine Aminotransferase                                   | Aspartate                                                                       |

The photosynthetic apparatus is sensitive to dehydration. Drought stress has a direct effect on carboxylating enzymes. The activities of enzymes RuBP carboxylase and PEP carboxylase decreased in the leaves of plants subjected to drought (Kaiser, 1987; Du et al., 1996). In sugarcane leaves, a decrease in the leaf water potential up to  $-0.37$  and  $-0.85$  MPa led to about a two to nine times decrease in the activities of RuBP carboxylase, PEP carboxylase, fructose-1,6-bisphosphatase, NADP malic enzyme, and orthophosphate dikinase, leading to an overall decreased rate of photosynthesis (Du et al., 1996). Drought stress alters carbon partitioning in plant parts owing to an alteration in the activities of sugar-metabolizing enzymes. In the leaves of sorghum plants, drought condition reduces sucrose formation owing to an inhibition in the activities of fructose-1,6-bisphosphatase and sucrose phosphate synthase (SPS) (Reddy, 1996). However, in potato tubers, a moderate drought stress leads to an activation of SPS and a stimulation of sucrose synthesis (Geigenberger et al., 1997). A more extreme drought stress in potato tubers leads to a further alteration in carbon partitioning, because it inhibits the activities of one or more of the enzymes involved in the terminal reactions of starch synthesis (Geigenberger et al., 1997).

Drought stress leads to oxidative damage in plants by inducing the production of active oxygen species and decreasing the activities of the antioxidant enzymes catalase, peroxidase, and SOD (Mali et al., 1980; Gogorcena et al., 1995). An increase in the capacity of the ascorbate regeneration system in cells by a *de novo* synthesis of monodehydroascorbate reductase (MDHAR), dehydroascorbate reductase (DHAR), and GR is one of the primary responses of plants to water deficit so as to mitigate oxidative stress (Boo and Jung, 1999; Sharma and Dubey, 2005a). Ascorbate peroxidase (APX) serves as an important component of the antioxidative defense system under drought stress in plants (Sharma and Dubey, 2005a). An examination of the involvement of activated oxygen in the drought-induced damage of pea nodules indicated that drought stress ( $-2.03$  MPa) caused a decrease in the activities of catalase (25%), APX (18%), DHAR (15%), GR (31%), and SOD (30%) with a simultaneous decrease in the contents of ascorbate (59%), reduced glutathione (57%), and oxidized glutathione (38%) (Gogorcena et al., 1995). The overproduction of antioxidant enzymes in order to scavenge reactive oxygen species (ROS), which are greatly produced under drought, provides an elegant approach to engineer plant species for drought stress tolerance. Transformed rice plants expressing pea manganese SOD have been shown to be more resistant to drought stress (Wang et al., 2005) compared with normal plants.
